SCHEDULING CANNABIS: A PREPARATORY DOCUMENT FOR FDA’S 8-FACTOR ANALYSIS ON CANNABIS

A SCIENTIFIC APPROACH FOR CONGRESS, DRUG ENFORCEMENT ADMINISTRATION, AND DEPARTMENT OF JUSTICE

Reviewed by Jahan Marcu, Ph.D., Ethan Russo MD, Lumir Hanus, Ph.D., Roger Pertwee, Ph.D., Steph Sherer, and Jason Schechter, Ph.D.
The research and analysis in this report was conducted by
Americans for Safe Access Foundation, a 501(c)(3) non-profit organization.

Publication date July 2016

With over 100,000 active members in all 50 states, Americans for Safe Access (ASA) is the largest
national member-based organization of patients, medical professionals, scientists and concerned
citizens promoting safe and legal access to cannabis for therapeutic use and research. ASA works
to overcome political and legal barriers by creating policies that improve access to medical
cannabis for patients and researchers through legislation, education, litigation, grassroots
actions, advocacy and services for patients and their caregivers, the medical cannabis industry,
and governments.

IV. Findings and Recommendations ................................................................................................................ 83
I. INTRODUCTION

Over the past decade, national polls in the United States (U.S.) have consistently ranked support for medical Cannabis among Americans at around 80%. A recent national poll showed that support for medical Cannabis now stands at 89% [1]. Over 300 million Americans live in states with some kind of law allowing for the use of medical Cannabis and over 2 million patients are legally accessing medical Cannabis under their physician’s supervision.

Federal laws and regulations surrounding the medical use of Cannabis have been based on politics rather than science dating back to the passage of the Marijuana Tax Act of 1937. Today, Cannabis remains a Schedule I drug under the Controlled Substance Act (CSA), which means it has no accepted medical use. Various efforts to reschedule Cannabis in the U.S. based on medical and scientific information have consistently been stymied by the Drug Enforcement Administration (DEA).

In April of this year, the DEA reported to Congress that they will be issuing a response to yet another rescheduling petition by mid-year 2016. This comes more than four years after receiving a petition from elected officials. This is an opportunity for the DEA to move Cannabis to a less-restrictive schedule (or removed from the CSA entirely) in order to boost research on the drug and the development of Cannabis products that doctors could openly recommend or eventually prescribe. However, the DEA continually moves away from a sensible research and public health approach to Cannabis[2]. Past reports on Cannabis research provided by the DEA have not included enough of the modern scientific articles published in the last 20 years and cites poorly designed studies that other researchers have failed to reproduce. Additionally, the DEA largely uses its own media and other non-scientific information to support its policy decisions on research and medical uses.

The DEA has little to risk by recommending that Cannabis be placed in another schedule status. Rescheduling would not legalize Cannabis, would not make Cannabis possession or cultivation by non-qualified or non-licensed individuals any less illegal under federal law, and it would be unlikely to end the standoff between the federal government and the states that have legalized Cannabis.

Medical Cannabis patients are not the only voices calling on the DEA to reschedule Cannabis. Governors, the U.S. Supreme Court, the American Medical Association, the American College of Physicians, and the American Public Health Association are just a few of the other institutions calling for the DEA to act[3]. However, given the DEA’s history on Cannabis and the fact that the DEA is the only federal agency that has not moved forward on the subject of Cannabis, we are not anticipating a wholly scientific response.

Americans for Safe Access (ASA) has pulled together world experts to create our own 8-factor analysis. In the following report, hundreds of modern peer-reviewed research studies are included for the analysis of the potential risks and benefits of Cannabis based on scientific evidence that researchers have largely been able to reproduce over the last decade. The independent 8-factor analysis provided here is a thorough peer-review document on the scientific data of Cannabis, containing all the information that is requested to consider rescheduling a drug. Our hope is that this document is used as a foundation for the public, Congress, and the Department of Justice to use to counter any DEA findings.
II. BACKGROUND

The U.S.'s history with Cannabis as a medicine dates back to the 1800's. Cannabis was a part of the American Pharmacopoeia until 1942. The political interference in the regulation of Cannabis as a medicine and subsequently the control of medical Cannabis research originates with the passage of the Marijuana Tax Act in 1937. Over the objections of the American Medical Association, the U.S. enacted the first federal law designed to restrict access to Cannabis, even for medical purposes[4].

Cannabis is now regulated by the CSA. At the time the CSA was being drafted in 1970, Assistant Secretary of Health, Roger O. Egeberg recommended that Cannabis temporarily be placed in Schedule I, pending the findings of the National Commission on Marihuana and Drug Abuse. President Richard Nixon appointed Pennsylvania Governor Raymond Shafer to chair the Commission. On March 22, 1972, the Commission presented its report, "Marijuana, A Signal of Misunderstanding," to Congress which concluded that the risks of using Cannabis were minimal and that general use did not jeopardize health, lead to experimentation with other drugs, or cause criminal activity, and specifically recommended the decriminalization of marijuana for personal use.

The recommendations provided in the Commission's report conflicted with many of the provisions provided in the Comprehensive Drug Abuse Prevention and Control Act and the CSA. President Nixon needed to reject the recommendations and formally declare a "war on drugs." Despite the Commission's recommendations to permit the medical and personal use of Cannabis, President Nixon enacted the Comprehensive Drug Abuse Prevention and Control Act.

Title II of the act, formally known as the CSA, places drugs into one of five categories, or schedules. Cannabis was restricted to Schedule I, reserved for substances with no medical value and a high potential for abuse; all use of the substance became strictly prohibited. Examples of other Schedule I drugs include heroin and LSD. Paradoxically, synthetic forms of THC, the most powerful psychoactive chemical component of Cannabis, are classified as Schedule III. Schedule III is reserved for drugs that exhibit medical value and have a mild potential for abuse. Other Schedule III drugs include ketamine, buprenorphine, hydrocodone, and codeine.

Cannabis may be reclassified in one of two ways; by an act of Congress or via administrative channels. The DEA could remove Cannabis from the list of Schedule I drugs through the rulemaking process in the same way they have handled dronabinol and other substances. However, the CSA also provides for a rulemaking process by which the general public may petition the U.S. Attorney General to reclassify Cannabis in accordance with the relevant scientific data.

Rescheduling and research petitions have previously been met with marginal success due to government agencies using antiquated and inefficient review processes. The first petition to reschedule was submitted in 1972 and was denied after 22 years of court appeals. In the summer of 1986, the DEA administrator initiated public hearings on Cannabis rescheduling. The hearings lasted two years, involving testimony from more than 60 researchers, doctors and their patients, and thousands of pages of documentation. On September 6, 1988, DEA Chief Administrative Law Judge Francis L. Young ruled that Cannabis did not meet the legal criteria of a Schedule I prohibited drug and should be reclassified. He declared that Cannabis in its natural form is "one of the safest therapeutically active substances known to man... It
would be unreasonable, arbitrary, and capricious for the DEA to continue to stand between those sufferers and the benefits of this substance...The provisions of the (Controlled Substances) Act permit and require the transfer of marijuana from Schedule I to Schedule II."

However, DEA Administrator John Lawn overruled Young's determination. Lawn said he decided against rescheduling Cannabis based on testimony and comments from numerous medical doctors who had conducted detailed research and were widely considered experts in their respective field, undisclosed meetings, and data. In 1994, the D.C. Court of Appeals finally affirmed the DEA Administrator's power to overrule a DEA Judge's decision, with little scientific evidence required to support the Administrator's position (Alliance for Cannabis Therapeutics v. DEA. 15 F.3d 1131). In summary, without disclosing the experts or the data they may have provided to overturn the Judge's decision, the petition to reschedule was officially denied by the DEA after an Administrator overturned the DEA court ruling.

The second attempt began in 1995 and was denied in April 2001. Another petition was received in 2002 (76 FR 40552), but was denied by the DEA in July 2011. In 2002, the Coalition for Rescheduling Cannabis, made up of several individuals and organizations, including ASA, filed a petition to reclassify Cannabis for medical use. That petition was denied by the DEA in July 2011, after ASA sued the Obama Administration for unreasonably delaying the answer. The appeal to the D.C. Circuit was the first time in nearly 20 years that a federal court reviewed the issue of whether adequate scientific evidence exists to reclassify Cannabis. Before the January ruling, the D.C. Circuit had never granted plaintiffs the right to sue when seeking reclassification of Cannabis.

After many years of frustration, patients and advocates began turning to their states for protection, rights, and access, eventually passing the first medical Cannabis law in 1996. Today 42 states, D.C., Puerto Rico, and Guam have passed some kind of law allowing the use of Cannabis. However, all of these state laws operate in conflict with the federal law and until 2014, following the passage of the Rohrabacher-Farr amendment to the Commerce, Justice, Science and Related Agencies Act (CJS), experienced federal enforcement including threats, raids, arrest, and prosecution by U.S. attorneys.

Patient advocates claim that Cannabis is treated unlike any other controlled substance and that politics have inappropriately dominated over medical science on this issue. Advocates point to a research approval process for Cannabis, controlled by the National Institute on Drug Abuse (NIDA), which is unique, overly rigorous, and effectively hinders meaningful pre-clinical and therapeutic research. In its appeal brief, ASA argued that the DEA has no "license to apply different criteria to marijuana than to other drugs, ignore critical scientific data, misrepresent social science research, or rely upon unsubstantiated assumptions, as the DEA has done in this case[5]."

ASA cited more than 200 peer-reviewed studies in its appeal, but the D.C. Circuit held that plaintiffs must produce evidence from Phase II and Phase III clinical trials -- usually reserved for companies trying to bring a new drug to market -- in order to show Cannabis' medical efficacy. Long term, Phase II and III studies on medical Cannabis will simply not be approved by the DEA or the NIDA under the current standards regulating their national monopoly on Cannabis produced for clinical research, unless Cannabis were to be rescheduled under the Conventions. Subsequently, ASA filed an appeal in January 2012, with the D.C. Circuit, which was heard on October 16th, 2012 and later denied[5].
In November of 2011, following the DEA’s denial of the 3rd rescheduling petition in 30 years, Governors Christine Gregoire (D-WA) and Lincoln Chafee (I-RI) jointly filed a petition to reclassify marijuana for medical use[6]. At a press conference announcing the filing, Governor Gregoire said, "It is time to show compassion and common sense, the people getting hurt in all of this are patients." In the rescheduling petition, the governors cited as many as 700 peer-reviewed research studies and reports on medical marijuana, and asked for public hearings, "so that the government can hear from doctors and scientists[5].”

In April 2016, the DEA responded to a letter from U.S. Senators in 2015 asking when a response would be given to the nearly five-year-old rescheduling petition. The DEA has said that they expect to issue their response to this petition my “mid-year 2016[5].”

It should be noted that while the DEA has failed to reschedule the whole plant form of Cannabis, the primary psychoactive drug on the plant, associated with nearly all of its negative side effects, was rescheduled to Schedule II in 1985 and Schedule III in 1999. This is a pure form of THC known as dronabinol.

Today more than 2 million patients have access to medical Cannabis and Cannabis products under state laws and over 300 million Americans live in states where this is an option. Many of these states have adopted standards for regulating Cannabis products in these markets as botanical standards with appropriate monographs. A recent United States Pharmacopoeia (USP) meeting cited the American Herbal Pharmacopoeia (AHP) Cannabis monograph as the current standard for regulating Cannabis as a medicine in the U.S. The USP cannot release an official monograph for Cannabis until it is rescheduled to a much less restrictive category[7].

Patient advocacy groups such as ASA, continue to put pressure on the U.S. Presidential administration, but are also lobbying Members of Congress to reclassify Cannabis for medical use. The Compassionate Access, Research Expansion, and Respect for States (CARERS) Act has also been introduced, which in addition to rescheduling Cannabis would allow states to establish Cannabis access laws and product safety regulations without interference by the federal government, and would remove current obstacles to research.
III. EVALUATING CANNABIS UNDER THE 8 FACTORS

FACTOR 1: CANNABIS’ ACTUAL OR RELATIVE POTENTIAL FOR ABUSE

The CSA defines Cannabis or marijuana as the following:

All parts of the plant Cannabis Sativa L., whether growing or not; the seeds thereof; the resin extracted from any part of such plant; and every compound, manufacture, salt, derivative, mixture, or preparation of such plant, its seeds or resin. Such term does not include the mature stalks of such plant, fiber produced from such stalks, oil or cake made from the seeds of such plant, any other compound, manufacture, salt, derivative, mixture, or preparation of such mature stalks (except the resin extracted therefrom), fiber, oil, or cake, or the sterilized seed of such plant which is incapable of germination. 21 U.S.C. 802(16).

The term “abuse” is not defined in the CSA. However, the legislative history of the CSA suggests the following in determining whether a particular drug or substance has a potential for abuse:

A. Individuals are taking the substance in amounts sufficient to create a hazard to their health or to the safety of other individuals or to the community.

B. There is a significant diversion of the drug or substance from legitimate drug channels.

C. Individuals are taking the substance on their own initiative rather than on the basis of medical advice from a practitioner licensed by law to administer such substances.

D. The substance is so related in its action to a substance already listed as having a potential for abuse to make it likely that it will have the same potential for abuse as such substance, thus making it reasonable to assume that there may be significant diversions from legitimate channels, significant use contrary to or without medical advice, or that it has a substantial capability of creating hazards to the health of the user or to the safety of the community.

In response to criteria for abuse as listed in a-d above, this section examines scientific publications related to toxicology, toxic and lethal dosing, abuse potential, adverse events, public health outcomes, and the role of Cannabis in psychiatric disorders (Anxiety, Depression, and Related Mood Disorders).
A. INDIVIDUALS ARE NOT TAKING THE SUBSTANCE IN AMOUNTS SUFFICIENT TO CREATE A HAZARD TO THEIR HEALTH OR TO THE SAFETY OF OTHER INDIVIDUALS OR TO THE COMMUNITY.

To determine the potential health hazards of a substance the human clinical toxicological data should be reviewed. The field of toxicology and related areas of study exist to define and codify the toxic effects exerted by administered drugs on the body and mind. The toxicology associated with Cannabis administration in humans has been extensively measured, via numerous pre-clinical and clinical studies. Using batteries of standardized tests, each study sought to compare brain health, function, and/or cognition of an individual affected with Cannabis to that of a “normally” functioning individual.[8-11].

There has been a historical and intensive effort to address those public health concerns related to the use of Cannabis and its effects on cognition. Negative effects on cognition or brain health (i.e., “toxic” effects) are most often defined as any statistically significant deviation from a “normal” mean.[12-16]. This mean is calculated by quantifying a battery of neuropsychological tests (i.e., memory, emotional cueing, and coordination tests) and brain imaging techniques (e.g. computed tomography [CT] or magnetic resonance imaging [MRI]). Whereas the former is useful for assessing aberrant behavioral, motoric, and learning effects, imaging is most useful in determining any abnormalities in physical brain structure and/or function caused by the intake of a drug.

Since concerns of Cannabis toxicity were first raised over perceived negative effects of Cannabis on brain health, unbiased investigation has remained somewhat problematic due to restrictions and objectives of traditional funding sources as they relate to Cannabis research.[17-20]. When negative ideological rhetoric guides health policy, rather than empirical scientific findings, reports of outcomes are often exaggerated or distorted prior to public presentation.[17,20-23]. Further, the results of extensive animal research may not appropriately represent the complex realities found in human populations, and thus proper human studies must be adequately controlled and conducted to define actual toxicology.[24].

Hence, the articles cited in this report are derived from evidence generated by controlled human studies, with a preference towards investigations of standardized preparations of Cannabis of known purity, provenance, content, and pharmacokinetic profile, over studies that are not properly controlled for variables or that do not include any dose-response, neuroimaging, neurochemical, or anatomical correlates.

An overview of existing research on the subject of potential harm to human brain health from the effects of Cannabis is provided below.
A lethal toxic overdose of Cannabis or its preparations has never been documented, nor has there ever been evidence that an attainable lethal dose of plant cannabinoids exists for humans. In basic research, human primary brain cells, cultured in vitro, exposed to excessively high amounts of THC – the primary active compound found in Cannabis – do not suffer any measurable toxic effects such as apoptosis or necrosis[25].

Drugs used in medicine are routinely given what is called an LD$_{50}$[26]. The LD$_{50}$ rating indicates at what dosage 50% of test subjects receiving a drug will die as a result of drug-induced toxicity. Whereas toxicological investigations are meant to evidence the LD$_{50}$ of a drug, currently there is no known LD$_{50}$ either for Cannabis or for any of its major components in humans. While a number of studies have attempted to determine an appropriate LD$_{50}$ rating for Cannabis in test animals, researchers have continuously been unable to give animals enough natural Cannabis to induce a death.

According to the U.S. Drug Enforcement Administration (DEA) hearing testimonials, the accepted theoretical calculations for an LD$_{50}$ of Cannabis were originally derived from a 1969 article by Todd Mikuriya, MD, which originated from a two-page 1968 position paper (without attributed authors) in the Journal of the American Medical Association[27,28]. In his paper, Mikuriya also estimated the lethal doses for Cannabis based on references to two previous papers by Loewe[29,30]. Neither prior to, nor since, has there been any real-life evidence of a human Cannabis toxicity-induced death to validate Mikuriya’s estimated LD$_{50}$.

At present, it is estimated that the human toxicity of Cannabis is around 1:20,000 or 1:40,000. In layman terms, this means that in order to induce death, a Cannabis smoker would have to consume 20,000 to 40,000 times as much Cannabis as is contained in one Cannabis cigarette[31-33].

A U.S. NIDA-supplied Cannabis cigarette weighs approximately 0.9 g. Therefore, a person would have to consume nearly 1,500 pounds of Cannabis within a 15-minute period to induce a theoretically lethal response. Unlike opiates, Cannabis compounds, such as THC, do not depress respiration and cannot depress respiratory drive due to sparse receptor density in medullary respiratory centers of the human brain[34,35]. In practical toxicological terms, Cannabis alone simply cannot induce a lethal outcome as a result of drug-related toxicity.

Based on current understanding of basic toxicity research – sedation, cytotoxicity, genotoxicity, etc. – Cannabis and its components seem to have a uniquely wide safety margin[36-39]. To date, there has never been a single well-documented case of human fatality attributable to an overdose of Cannabis or its components, and no experimental or non-extrapolated LD$_{50}$ can be attributed to a toxic or lethal overdose of Cannabis or a preparation thereof.
Clinical Toxicological Studies of Cannabis and Brain Function: IQ and Psychological Tests

Numerous assessments of brain function and IQ have been carried out in cohorts or groups studied from nearly every part of the world. The available evidence on effects of Cannabis on the brain come from wide-ranging human studies in the Caribbean, Latin America, North America, the Mediterranean, South Asia (Australia, New Zealand) and Europe. Most studies find a significant difference in brain function related to current Cannabis use (i.e., the day of the test), but show no consistent, reproducible, or significant long-term effects when study participants remain abstinent[40]. Results of long-term Cannabis use on brain health are often confusing and not statistically significant. As one clinical researcher noted in a review, “current human observations on the effects of marijuana [Cannabis] on development are sparse and contradictory[41].

A review and summary of the existing human clinical evidence is provided below:

Clinicians in Jamaica administered a series of 19 neuropsychological tests to both chronic Cannabis users and naïve controls with no major differences between groups, except that the Cannabis users scored significantly higher on the Wechsler Adult Intelligence Scale (WAIS) Digit Span performance (p<0.05)[42]. The authors concluded that “there is no evidence that long-term use of Cannabis is related to chronic impairment[42].”

A study of Cannabis hashish users and naïve controls, matched for age and socio-economic status, noted no differences in total on Performance IQ (PIQ) scores on the WAIS, but the controls performed somewhat better on three subtests involving Comprehension, Similarities, and Digit Symbol Substitution[43]. However, with less than a 7 PIQ difference, normally found in Greece population studies, the authors were led to conclude that “these observations do not provide evidence of deterioration of mental abilities in hashish users[42].”

An extensive battery of neuropsychological tests showed no Cannabis-induced pathological changes in a Costa Rican population study. The authors stated, “we failed to uncover significant differences between user and nonuser groups – even in those subjects who had consumed Cannabis for over 18 years[44].” When a follow-up study was performed on some of the members of this long-using cohort, initially there were significant differences claimed, but a subsequent critical analysis of the results reported that the effects were reduced below a meaningful statistical significance[45,46].

Another study investigated the effects of Cannabis on “cognitive decline” in 1,318 adults under the age of 65, over a period of 12 years. Using the Mini-Mental State Examination (MMSE), the study evidenced no significant differences in the degree of decline amongst heavy, light, and non-users of Cannabis[8,47].

The book Cannabis and Cognitive Functioning is a series of summarized studies in which the author studied subjects using Cannabis at least twice a week, on average, for a period of 3 years[48]. The author stated (p. 227), “the weight of the evidence suggests that the long-term use of Cannabis does not result in any severe or grossly debilitating impairment of cognitive function.” The author did note more subtle difficulties in attention parameters, including an increased predilection for subtle distraction, loose
associations, and likelihood of intrusion errors during memory tasks. In another review of cognitive effects of *Cannabis* by the same author, it was observed that "the long term risks for most users are not severe and their effects are relatively subtle...[49]."

A North American study on individuals aged 30-55 years old divided participants into 3 groups: 1) current daily users who had smoked *Cannabis* at least 5,000 times, 2) former users who had smoked *Cannabis* at least 5,000 times but had used *Cannabis* no more than 12 times in the prior 3 months, and 3) non-users, who had not consumed *Cannabis* more than 50 times in their lives[40]. Subjects underwent a 28-day washout period with tests performed at 0, 1, 7, and 28 days of abstinence. This study found that "users showed virtually no significant differences from control subjects on a battery of 10 neuropsychological tests[40]." The authors also concluded that former heavy users who had not consumed *Cannabis* in the last 3 months "showed no significant differences from control subjects on any tests during testing days." This study suggests that any induced cognitive deficits attributable to *Cannabis* use exist as reversible phenomena, associated with recent *Cannabis* exposure and not due to any irreversible toxicity.

A New Zealand birth cohort study, involving 1,037 participants, found an average drop in IQ of 8 points (within a somewhat higher degree of variability; +/- 14 IQ points) at age 38 in *Cannabis* users that had used at least 4 days per week, versus non-users[50]. The authors stated, “a limitation is that we obtained information on past-year *Cannabis* dependence and self-reported frequency of *Cannabis* use with no external validation of use (e.g., biological assays)[50]."

Another New Zealand study of 111 participants found that “current users of *Cannabis* containing CBD (a second and non-psychoactive cannabinoid found in natural *Cannabis*), as well as former users, showed no structural or neurochemical hippocampal differences compared with controls[12].” The experimental cohort that was exposed to THC and no reported CBD demonstrated temporary changes in hippocampal volumes, but these effects were not significant if the users reported using *Cannabis* containing CBD. The authors stated "users exposed to CBD and former users did not differ from controls on any measure[12]."

Most recent findings suggest that low to moderate adolescent *Cannabis* use is associated neither with IQ nor with lower educational performance once adjustment is made for potential confounding data – in particular, adolescent cigarette use[11]. A sample of 2,235 teenagers participated in a United Kingdom (UK) study, which adjusted for pre-exposure to *Cannabis*, cigarette use, alcohol use, childhood mental-health symptoms, and behavioral problems. *Cannabis* use itself was not found to be causally related to lower IQ or poorer educational performance. The authors concluded that “modest *Cannabis* use in teenagers may have less cognitive impact than epidemiological surveys of older cohorts have previously suggested[11]."

In regards to long-term cognitive effects of *Cannabis* use, a 2012 literature review of 11 peer-reviewed studies evaluating *Cannabis’* potential impact on cognitive function of over 1,000 subjects concluded, “The results of our meta-analytic study failed to reveal a substantial, systematic effect of long-term, regular *Cannabis* consumption on the neurocognitive functioning of users who were not acutely intoxicated[51].”

No scientifically significant negative neuropsychological sequelae have yet been attributable to *Cannabis*
usage. Arguably, some of these studies remain limited by a number of factors that need to be controlled in future investigations. Primarily, Cannabis use and dosing needs to be confirmed in users with biological and chemical tests, as issues of dosing and patterns of use are confounding factors when not adjusted for. "The results of our meta-analytic study fail[s]...to reveal a substantial, systematic effect of long-term, regular Cannabis consumption on the neurocognitive functioning of users who were not acutely intoxicated[51]."

---

**Review of Toxicology of Cannabis Use in Brain Imaging Studies**

Several studies have looked at small patient cohorts and have failed to find evidence of either permanent or consistent types of brain damage, abnormalities, structural brain changes, or brain tissue volume of either white or grey matter[48,52-56]. Human studies on brain structural and functional changes employing CT scans or MRIs are summarized below.

A 1977 study employed CT scans on 19 men with long durations of heavy Cannabis usage. Results showed no significant changes in either the ventricles or sub-arachnoid spaces[53]. The authors criticized a prior study for lacking controls on antecedent head trauma or other causes of neurological damage[54]. In the same issue of the *Journal of the American Medical Association*, an additional study on another cohort of 12 heavy Cannabis smokers displayed no CT abnormalities[55].

In 1983, brain CT scans were studied from 12 subjects who smoked more than 1 g of Cannabis daily for 10 years. Out of the 12 subjects, only 1 subject with a concomitant history of alcoholism showed any abnormalities compared to controls[56,57].

In 2000, no abnormalities were ascertained in a study that employed automated imaging analysis with MRI to examine 18 young/heavy Cannabis users. The authors stated "frequent marijuana use does not produce clinically apparent MRI abnormalities or detectable global or regional changes in brain tissue volumes of gray or white matter, or both combined[58]." One of the leading experts in the field of Cannabis' cognitive effects and dependence, Dr. Nadia Solowij, stated in a 2001 publication that "there is no evidence from human studies of any structural brain damage following prolonged exposure to cannabinoids[48]."

A 2015 study based in Colorado – a U.S. state that allows Cannabis use for qualifying adults – examined brain morphology (via volume measurements) in a sample of 29 adult daily Cannabis users versus 29 non-users, and a sample of 50 adolescent daily users versus 50 non-users[59]. The researchers measured the following areas and structures of the human brain, each understood to be associated with Cannabis use, as follows: the grey matter, nucleus accumbens, amygdala, hippocampus, and cerebellum. The results showed no statistically significant differences between daily users and non-users, in either volume or shape, in any region of interest. The authors concluded, “the results indicate that, when carefully controlling for alcohol use, gender, age, and other variables, there is no association between marijuana use and standard volumetric or shape measurements of subcortical structures[59]."
Claims of brain damage and cerebral atrophy are not supported by current evidence. When controlling for pertinent variables such as age, gender, and history of alcohol use, research has not been able to show any association between the use of Cannabis and changes in subcortical structures[59].

Abuse Potential, Dependence Potential and Adverse Reactions in Humans

Cannabis dependence or Cannabis use disorders are an increasingly recognized problem, principally driven by Δ⁹-THC[60,61]. Although standardized Cannabis preparations such as nabiximols, dronabinol, and flower tops (Bedrocan; Dutch Cannabis) have a very low street value and diversion is rare, all THC containing medicines share a dependence liability. However, fundamental differences exist between patients receiving licensed or regulated medicine and commercial/recreational smokers of Cannabis obtained in the black market[60,61]. Of clear significance are variations in active cannabinoid and other constituents, and purity. There is also a fundamental difference in the motivations of users; recipients of a medicine typically seek to relieve their symptoms without experiencing cognitive disturbance[62].

Currently available standardized preparations of Cannabis have been found to have a very low abuse potential. Two examples of this are dronabinol an oral preparation of THC isolated from the Cannabis plant, and nabiximols, a recently licensed Cannabis medicine, approved and available in 27 countries, that contains equal amounts of THC and the synergistic non-intoxicating CBD. Dronabinol has also been proposed, and has demonstrated efficacy in limited trials, as a treatment for Cannabis use disorders[63].

Cannabis strains that are inhaled can contain varying ratios of active constituents, and thus may vary in a range of effects and may therefore have a higher abuse potential than dronabinol or nabiximols[64]. CBD also demonstrates a low abuse potential and has been shown to not significantly enhance the effects of THC or positive subjective effects of Cannabis[65].

The incidence of intoxication and euphoria during clinical trials of nabiximols has been very low, reported by only 2.2% percent of patients[9]. Significant tolerance was not recorded during long-term dosing, and abrupt withdrawal from long-term use produced only mild and transient disturbance of sleep, mood, or appetite in a minority of subjects with no concomitant withdrawal syndrome[60].

No cases of abuse or diversions of these medicines have been reported. This reassuring profile with regard to abuse potential is consistent with clinical experience of nabilone and dronabinol, which have been available by prescription for decades[66]. In published research articles, abuse or diversion is reported as “rare and isolated” and no evidence of street market for these drugs has been detected.

In an abuse liability study of experienced Cannabis smokers, higher doses of nabiximols did show evidence of abuse potential in comparison with placebo, but scored consistently lower on a dose-for-dose basis than dronabinol. The apparent difference in risk profile is likely a consequence of the presence of CBD in whole Cannabis preparations. In brain imaging and cognitive studies, participants reporting use of Cannabis containing a significant content of CBD have been demonstrated not to differ from control subjects with respect to either brain volume or reported results on a battery of neuropsychological tests.
The evidence to date suggests that abuse or dependence of standardized, regulated, or licensed Cannabis preparations is likely to occur only in a very small proportion of recipients.

Compared to nabiximols, inhaled Cannabis preparations have a higher abuse potential. Nabiximols also exhibits less non-serious psychological side effects as compared to oral THC preparations such as dronabinol[31,67]. Although the presence of THC in Cannabis-based preparations could lead to abuse or dependence, this possibility has not yet emerged with significance in clinical trials of standardized preparations of Cannabis administered via either the oral or oral-mucosal route. This area of investigation would benefit from further exploration in greater detail of inhaled Cannabis preparations.

Serious and Non-Serious Adverse Events and the Use of Medical Cannabis Preparations

Under international guidelines, a “serious adverse event” is defined as any untoward medical occurrence that requires admission to a hospital or prolongation of an existing admission, causes congenital malformation, results in persistent or significant disability or incapacity, is life threatening or results in death. A “nonserious adverse event” is defined as any untoward medical occurrence in a patient or participant; the event need not have a causal relation to the treatment. The guidelines of the International Conference on Harmonization define the ‘expectedness’ of an adverse event, whereby an “unexpected” adverse event is one for which “the nature or severity ... is not consistent with the applicable product information[68,69].”

A recent investigation on a cohort of 215 individuals with chronic non-cancer pain examined the safety issues of a standardized herbal Cannabis product (12.5% THC). The standardized Cannabis was dispensed to eligible subjects for a one-year period. The control group consisted of participants with chronic pain, who were not dispensed Cannabis. The primary outcomes measured consisted of serious adverse events and non-serious adverse events. Secondary safety outcomes included pulmonary and neurocognitive function and standard hematology, biochemistry, renal, liver, and endocrine function. Other parameters included pain and other symptoms, mood, and quality of life. The median daily Cannabis dose was 2.5 g/d. There was no difference in risk of serious adverse events between groups. Medical Cannabis users were at an increased risk of non-serious adverse events, but these were mild to moderate. There were no differences in secondary safety assessments. The authors conclude, “This study suggests that the adverse effects of medical Cannabis are modest and comparable quantitatively and qualitatively to prescription cannabinoids. The results suggest that Cannabis at average doses of 2.5g/d in current Cannabis users may be safe...[39].”

The next set of identified adverse events discussed and used in the subsequent text were part of an investigation that coded the adverse events to the highest standard of reporting, according to the Medical Dictionary for Regulatory Activities headings “system organ classes” and “preferred terms[70,71].”
Verification of data extraction methods and use of coding according to the Medical Dictionary for Regulatory Activities were verified by a medically qualified reviewer.

Numerous reports have attributed adverse effects to Cannabis as an associated risk factor for psychosis and neurocognitive effects[39]. Many of these reports either focus on recreational use without requiring a standardized Cannabis product, or do not employ biological assays to confirm and assess recent Cannabis use in participants[38,57,72,73]. The research summary and review below consists mainly of controlled, blinded studies on adverse events concerning medical Cannabis preparations.

A meta-analysis of 31 studies (23 randomized controlled trials and 8 observational studies) included an analysis of Cannabis side effects (such as dizziness and acute anxiety)[9]. Cannabis medicines included in the analysis comprised of an oral-mucosal Cannabis spray preparation (nabiximols), oral THC (dronabinol), and oral THC-CBD. The median duration of Cannabis-based medicine exposure was 2 weeks (ranging from 8 hours to 12 months). The meta-analysis identified a total of 4,779 adverse events reported amongst participants assigned to the intervention.

Most of the adverse events, 4,615 (96.6%), were not serious[9]. Amongst these studies, the most commonly reported non-serious side effect was dizziness (15.5%). However, the study did find 164 serious adverse events. The most frequent categories of serious adverse events among medical Cannabis product users were respiratory (16.5%), gastrointestinal (16.5%), and nervous system disorders (15.2%), whereas nervous system disorders were the most frequently reported among the control group (30.0%). Relapse of multiple sclerosis (21 events [12.8%]), vomiting (16 events [9.8%]), and urinary tract infection (15 events [9.1%]) were the most commonly reported serious adverse events among people assigned to receive medical Cannabis preparations. There was no evidence of a higher incidence of serious adverse events following medical Cannabis use compared with controls among a meta-analysis of adverse events and medical Cannabis preparations[9].

In January of 2016, a clinical trial with a synthetic modulator (BIA 10-2474) of the endocannabinoid system was abruptly interrupted[74]. This synthetic drug inhibited the activity of fatty acid amide hydrolase (FAAH), the enzyme responsible for the degradation of the endocannabinoid anandamide (AEA, arachidonoyl ethanolamide), thus increasing the concentrations of AEA available to stimulate the endocannabinoid system[75]. All of the pharmaceutical companies with active programs testing FAAH inhibitors voluntarily suspended their trials after the disaster of BIA 10-2474 from the Portuguese pharmaceutical company Bial, whose phase I study in healthy subjects in France left one person brain dead and five others hospitalized[76].

FAAH is also responsible for the degradation of many other fatty acid amides in the brain and body. Inhibiting FAAH not only increases the concentration of anandamide, but also the concentrations of other fatty acid amides[77]. As the mechanism of action is entirely different from that of THC, which binds to cannabinoid receptors[78], synthetic modulators of the endocannabinoid system should be seen as entirely different to cannabinoids or Cannabis in terms of their potential side effects and should be judged separately.

Short-term use of existing standardized medical Cannabis and Cannabis products appear to increase the
risk of non-serious adverse events. Risks associated with long-term Cannabis use are poorly characterized in published clinical trials and observational studies; however, the cognitive effects observed in long-term users do not appear to be permanent in nature[40]. With the exception of very limited studies on synthetic endocannabinoid system modulators, Cannabis medicines do not appear to cause significant serious adverse events. Three tables summarizing documented effects on controlled studies with a standardized preparation of Cannabis are provided below.

**Toxicology, Adverse Events, and Abuse**

While few significant negative health sequelae are attributable to long-term Cannabis usage, ongoing human use of cannabinoids as medicine will continue to elucidate the emergence of negative effects. Clinically relevant risks and public health concerns associated with long-term cannabinoid use have yet to be satisfactorily demonstrated, perhaps due to the comparatively mild withdrawal effects of THC, its primary active compound. Based on current understanding of basic toxicity research, Cannabis and its components seem to have a uniquely wide safety margin. Notably cannabinoids do not depress respiratory drive, unlike opiates[34]. To date, there has never been a single documented case of human fatality attributable to an overdose of Cannabis or its cannabinoids. Results of meta-analytic studies have thus far failed to reveal any substantial, systematic effect of long-term, regular Cannabis consumption that is not reversed by abstinence.

Pulmonary issues associated with Cannabis smoking include chronic bronchitis, particularly chronic cough, and sputum production, with more variable effects on wheezing and generally negative effects on breathlessness. However, these issues are avoidable by using vaporizer/volatile technology or alternative routes of administration[79,80]. Importantly, lifetime use of Cannabis smoking is not associated with an increase incidence of lung cancer[81].

Another confounding factor affecting a clearer understanding of long-term, chronic Cannabis use is the prevalence of serious adverse events concerning untoward Cannabis contaminants. Lung infection from bacterial and fungal contamination of plant materials, lead and other heavy metals poisoning, bronchial irritation from foreign particulate matter such as tiny pieces of broken glass, concomitant use of tobacco, calamus and other cholinergic compounds[82,83]– some side effects, both serious and non-serious, are due to contaminated products found on the black market.

Access to Cannabis products manufactured under appropriate quality assurance/quality control conditions – such as those properly standardized Cannabis products now available in 27 countries – are associated with significantly lower prevalence of negative health issues, both serious and non-serious. The illegality of Cannabis is a threat to the safety of using Cannabis as a medicine. Programs for supporting qualified individuals to access Cannabis, global product safety guidelines, or licensed/licensed Cannabis testing facilities help to ensure that the rights of medical consumers are respected.

**How Safe is Cannabis?**

Research continues to demonstrate that Cannabis and its preparations have an excellent safety profile. According to the Drug Awareness Warning Network Annual Report, published by the Substance Abuse and Mental Health Services Administration (SAMHSA), which contains a statistical compilation of all drug deaths that occur in the U.S., not a single death has ever been recorded due to the use of Cannabis.

DEA Chief Administrative Law Judge, Francis Young, in response to a petition to reschedule Cannabis under federal law concluded in 1988 that, “In strict medical terms marijuana is far safer than many foods we commonly consume.... Marijuana in its natural form is one of the safest therapeutically active substances
known to man. By any measure of rational analysis marijuana can be safely used within the supervised routine of medical care[32].”

Public Health Outcomes

The effects of drug or substance abuse related to public health outcomes should be considered and evaluated in comparison to other drugs and substances[24,84-86]. Previous analysis has shown that Cannabis smokers are 2.6 times more likely to have a psychotic-like experience than compared to non-smokers[87,88]. By comparison, people who smoke tobacco are 20 times more likely to get lung cancer than those who do not smoke. To put this in perspective, over 5,000 men, 20-25 years old would need to stop using the drug in order to ostensibly prevent one episode of schizophrenia. Along with this is the paradox that while cases of schizophrenia have decreased in the last 30 years, Cannabis use has increased substantially amongst like populations[87,88].

Proper assessment of the harms caused by the misuse of drugs can inform policy makers when making decisions towards health, policing, and social care. The research study and figures discussed below apply a multi-criteria decision analysis (MCDA) model to demonstrate a range of drug harms. This research, based in the UK, provides the most recent comprehensive research published on comparing the harms of various drugs[89,90].

Figure 1) Evaluation criteria organized by harms to users and harms to others, and clustered under physical, psychological, and social effects. The above figure demonstrates how drug harm is measured; essentially the two major factors are harm to the drug user and harm to others.

ASA | Scheduling Cannabis: A Preparatory Document for FDA’s 8-Factor Analysis on Cannabis

Figure 2: Overall weighted scores for each of the drugs
The colored bars indicate the part scores for each of the criteria. The key shows the normalized weight for each criterion. A higher weight indicates a larger difference between the most harmful drug on the criterion and no harm. CW=cumulative weight. GHB=γ hydroxybutyric acid. LSD=lysergic acid diethylamide. The scores were generated according to the International Classification of Diseases, tenth revision of the Diagnostic and Statistical Manual of Mental Disorders, fourth revision. Nutt et al. (2010). Drug harms in the UK: a multicriteria decision analysis. The Lancet, 376(9752), 1558–1565.

Definitions: Drug-specific mortality Intrinsic lethality of the drug expressed as ratio of lethal dose and standard dose (for adults). Drug-related mortality The extent to which life is shortened by the use of the drug (excludes drug-specific mortality)—eg, road traffic accidents, lung cancers, HIV, suicide. Drug-specific damage Drug-specific damage to physical health—eg, cirrhosis, seizures, strokes, cardiomyopathy, stomach ulcers. Drug-related damage to physical health, including consequences of, for example, sexual unwanted activities and self-harm, blood-borne viruses, emphysema, and damage from cutting agents. Dependence The extent to which a drug creates a propensity or urge to continue to use despite adverse consequences (ICD 10 or DSM IV). Drug-specific impairment of mental functioning Drug-specific impairment of mental functioning—eg, amphetamine-induced psychosis, ketamine intoxication. Drug-related impairment of mental functioning Drug-related impairment of mental functioning—eg, mood disorders secondary to drug-user’s lifestyle or drug use. Loss of tangibles Extent of loss of tangible things (eg, income, housing, job, educational achievements, criminal record, imprisonment). Loss of relationships Extent of loss of relationship with family and friends. Injury Extent to which the use of a drug increases the chance of injuries to others both directly and indirectly—eg, violence (including domestic violence), traffic accident, fetal harm, drug waste, secondary transmission of blood-borne virus. Crime Extent to which the use of a drug involves or leads to an increase in volume of acquisitive crime (beyond the use-of- drug act) directly or indirectly (at the population level, not the individual level). Environmental damage Extent to which the use and production of a drug causes environmental damage locally—eg, toxic waste from amphetamine factories, discarded needles. Family adversities Extent to which the use of a drug causes family adversities—eg, family breakdown, economic wellbeing, emotional wellbeing, future prospects of children, child neglect. International damage Extent to which the use of a drug in the UK contributes to damage internationally—eg, deforestation, destabilisation of countries, international crime, new markets. Economic cost Extent to which the use of a drug causes direct costs to the country (eg, health care, police, prisons, social services, customs, insurance, crime) and indirect costs (eg, loss of productivity, absenteeism). Community Extent to which the use of a drug creates decline in social cohesion and decline in the reputation of the community.
Members of the UK’s Independent Scientific Committee on Drugs, and two invited specialists, met for a 1-day interactive workshop to score 20 drugs on harms assessment. This panel of drug-harm experts were convened to establish scores for 20 representative drugs that were relevant to the UK and which span the range of potential harms and extent of use. The harms were assessed according to a set of 16 criteria developed by the Advisory Council on the Misuse of Drugs (the UK Government committee on drug misuse). Of the 16 criteria, nine related to the harms that a drug produces in the individual and seven were in relation to the harms of another. Drugs were scored out of 100 points, and criteria were weighted to indicate their relative importance. Overall, alcohol showed to be the most harmful drug (overall harm score 72), with heroin (55) and crack cocaine (54) in second and third places.

Provided by Nutt et al. (2010), and created from data obtained from the workshop, Figure 2 shows a comparison amongst drugs of abuse across different scheduling and control status, with each colored bar representing a different criterion. For example, Drug-Specific Mortality, representing reported average occurrences of deaths from the substances over time, is on the top of each column. Alcohol, heroin, butane, and GHB display a notable association with higher risk of death from consumption, while Cannabis, anabolic steroids, khat, and LSD show very low or no association with mortality. A limiting factor of this and other data discussed here is that the substances are only scored for harm and weighted without scores or criteria regarding medical use. Another important limiting factor is that Nutt et al.’s calculations of Cannabis harm are somewhat overstated due to their consideration of legal harms in their process. Ideally, only medical factors would be the sole determinants of risk.

This is not the first study of its kind and previous research found similar results. The findings of Nutt et al. (2010) lend support to previous work in the UK, the Netherlands, the U.S. and elsewhere, confirming that the present drug classification systems have little relation to empirical evidence of harm[57,87-93]. These studies also subscribe to the conclusions of previous expert reports, that aggressively targeting alcohol harms is a valid and necessary public health strategy.

CANNABIS AND PSYCHIATRIC DISORDERS (ANXIETY, DEPRESSION, AND RELATED MOOD DISORDERS)

Human studies on the effects of Cannabis on anxiety and depression or mood disorders include studies on THC, CBD, and whole plant material. Dosing consisted of a range between 5mg-30mg oral THC and a single clinical study looked at 0.5mg/kg THC for changes in mood and related behavior. For CBD, clinical studies examined oral doses ranging between 60mg-600mg and 1mg/kg for improvements in related mood disorders. Conversely, THC with the CB1 receptor antagonist, rimonabant is capable of decreasing stress and anxiety levels at an oral dose of 70mg.

Anxiety and Mood Disorders

The effects of Cannabis on anxiety and depression may depend on the ratio of certain cannabinoids, the individual user, and the context in which it is used. One of the active ingredients of Cannabis can cause an acute and short-lasting episode of anxiety, which often resembles panic, in naïve users. For a naïve user, a dose of oral THC that is likely to start to induce anxiety is >5mg synthetic Δ⁹-THC (for a man of average weight) and a higher dose could induce both panic attacks and paranoias[94]. However, the same is not necessarily true for all cannabinoids.

In a study with 10 treatment-naïve patients with generalized social anxiety disorder, 400mg oral CBD was shown to reduce anxiety compared to placebo. This anxiolytic effect was associated with significantly reduced regional cerebral blood flow (measured by uptake of 740MBq of 99mTc-ECD) in the left parahippocampal gyrus, hippocampus, and inferior temporal gyrus, while increasing cerebral blood flow (ECD uptake) in the right posterior cingulate gyrus[95]. Similarly, a study of 24 patients with social anxiety disorder found an association between CBD (600mg; n=12) and decreases in anxiety within the context of public speaking task[96].

In 1974, an interactive study between CBD and THC showed that CBD (60 mg), added to Δ⁹-THC (30 mg), changed the symptoms induced by THC alone in such a way that the subjects receiving the mixture showed less anxiety and more pleasurable effects [97]. In 1982, a study confirmed a similar effect with CBD (1 mg/kg), co-administered with THC (0.5 mg/kg), and this combination also significantly reduced anxiety indices in healthy volunteers[98].

An early study on Cannabis use in Jamaica revealed no significant differences between a group of 30 users, and matched controls with respect to mood, thought, or behavior [99]. An international study funded by the National Institute on Drug Abuse, examined a group of 47 long-term hashish users in Greece. Differences in the number of users within defined psychopathology, as compared to controls was accounted for by “personality disorders,” with more psychiatric abnormalities being observed in the moderate user group as compared to heavy users [100,101]. A few years later, another study documented that Cannabis users in Costa Rica believed that use helped with depression. No significant adverse effects, or development of adverse health effects resulting from Cannabis use were observed[44].

The effects of THC are not consistent and often may misrepresent the effects of whole Cannabis[102]. In a
study of oral THC, healthy volunteers received two doses of THC (7.5 and 15mg by mouth) or placebo, across separate sessions, before performing tasks assessing facial emotion recognition and emotional responses to pictures of emotional scenes[102]. In this three-session, double-blind, placebo-controlled study, THC significantly impaired recognition of facial fear and anger, marginally impairing recognition of sadness and happiness. The subjective responses to THC were not consistently positive – of the 25 study participants, 15 indicated a desire to take the 7.5mg dose again, whereas only 11 out of 25 did so at the higher 15 mg dose. Just over half of the participants identified THC as “marijuana-like” (7.5mg: 56%; 15mg: 52%). This study parallels many other findings on this subject – the paradox between dampened amygdalar reactivity and increased physiological indicators of emotional response remains a mystery to be resolved. The authors concluded that this property could potentially increase the appeal of Cannabis to certain users. As Cannabis use can lead to reduced sensitivity to anxiety-provoking emotional signals in some people, this may facilitate certain social interactions, especially amongst individuals with social inhibition or related disorders.

It has been well demonstrated that ‘blocking’ or interfering with CB₁ receptor signaling can increase anxiety. One study documented that the CB₁ receptor antagonist/inverse agonist, rimonabant, increases anxiety induced by public speaking in healthy humans. The anxiogenic effects occurred selectively during anticipatory and performance speech, without interfering with the pre-stress phase, meaning that the drug effects occurred selectively in response to an aversive situation[103].

Inhaled Cannabis and mucosal sprays – with precise amounts of key cannabinoid ingredients – do not induce the same side effects as pure THC controls[104]. Research suggests that a Cannabis “overdose” (i.e., anxiety, panic attack, etc.) can be treated (or prevented prophylactically) with foodstuffs such as pine nuts, lemons, basil and/or orange juice, as these foodstuffs share many relevant, pharmacologically active compounds[104].

Similar to the literature on the effects on Cannabis on anxiety, the effects of Cannabis on mood disorders are contradictory. For example, a group of authors published case reports suggesting Cannabis can cause an acute depressive reaction in those with underlying depression. However, their later case reports suggest Cannabis use can improve symptoms of bipolar disorders[31,101,105]. Cross sectional studies suggest that depression is associated with Cannabis use, and that Cannabis consumption is related to an increased risk of depression later in life[13,106]. Likewise for anxiety, it has been noted that “Frequent cannabis users consistently have a high prevalence of anxiety disorders and patients with anxiety disorders have relatively high rates of cannabis use [94].” It is unknown whether Cannabis use leads to a greater incidence of depression and anxiety later in life. In one survey, Cannabis use and depression were not associated once medical use was taken into account[107].

In some cases, an illness (and not the use of Cannabis) may be causative factor for depression. Though there is a modest increase of risk amongst problematic users of developing depression or an anxiety disorder later in life, a recent meta-analysis found that that small, but statistically significant association between Cannabis and anxiety hinged on the inclusion of a single study[108]. While Cannabis may provide some benefit to anxiety or depressive/mood disorders in some individuals, the true relationship between Cannabis use and anxiety and depressive disorders later in life remains unsubstantiated by current research. Similar to anxiety, differential effects of Cannabis on depression may be due to differences in
cannabinoid composition. Indeed, CBD has been shown to produce anti-depressant like effects similar to imipramine[109,110].

**Suicide and Suicidal Ideation**

Recent epidemiological work found no relation between the number of medical Cannabis users and completed suicides[111]. In fact, U.S. states that legalized the use of medical Cannabis were shown to have lower rates of suicide among men between the ages of 20 and 39, when compared to states that did not legalize medical Cannabis use[112]. Research among non-medical Cannabis using populations has received considerably more attention. Unfortunately, while some studies have shown associations between Cannabis use and heightened suicide ideation and attempts, a number of studies have either failed to control for confounds or, when they have, reported no association between Cannabis use and suicide[113-118].

**Post-Traumatic Stress Disorder**

There has been a recent emergence of empirical studies on the effects of Cannabis for symptoms of Post-Traumatic Stress Disorder (PTSD), borne primarily out of the observation that individuals with PTSD report using Cannabis to cope with PTSD symptoms; specifically, hyperarousal, negative affect, and sleep disturbances[119-121]. Indeed, empirical work has consistently demonstrated that the endocannabinoid system plays a significant role in the etiology of PTSD, with greater availability of cannabinoid type 1 receptors documented among those with PTSD than in trauma-exposed or healthy controls[122,123].

**B. THERE IS NO SIGNIFICANT DIVERSION OF THE DRUG OR SUBSTANCE FROM LEGITIMATE DRUG CHANNELS.**

Currently available standardized preparations of Cannabis have been found to have a very low potential to be converted into controlled substances of abuse, and there is no supporting evidence of street markets existing for such psychoactive preparations[60]. Two examples of this are dronabinol and nabiximols. Dronabinol, an oral preparation of THC, is isolated from the Cannabis plant or synthetically produced. Nabiximols, a recently licensed Cannabis medicine, approved and available in 27 countries, contains equal amounts of THC and the synergistic non-intoxicating CBD. Dronabinol has also been proposed, and has demonstrated efficacy in limited trials, as a treatment for Cannabis use disorders[63]. There were no available peer-reviewed reports documenting a significant street market or conversion of medical Cannabis products distributed through pharmacies and dispensaries in Canada, U.S. Holland or from any other of the numerous countries that have Cannabis access programs, at the time this report was written.

Whole plant Cannabis strains that are inhaled can contain varying ratios of active constituents, and thus may vary in a range of effects, and may therefore have a higher potential for conversion into other controlled substances than dronabinol or nabiximols[64]. CBD also demonstrates a low abuse potential and has been shown to not enhance significantly the reinforcing effects of THC or positive subject effects of Cannabis[65].
No cases of diversion of Cannabis-based medicines (Dronabinol, Sativex, Epidiolex, Rimonabant, or Cannabis from NIDA’s marijuana operation at the University of Mississippi) have been reported[60]. This reassuring profile is consistent with clinical experience of nabilone and dronabinol, which have been available by prescription for decades[66]. In summation, published research articles report abuse or diversion as “rare and isolated” and the street market for these psychoactive drugs was determined to be very low, if it exists[60,124].

C. INDIVIDUALS ARE NOT TAKING THE SUBSTANCE ON THEIR OWN INITIATIVE, RATHER ON THE BASIS OF MEDICAL ADVICE FROM A PRACTITIONER LICENSED BY LAW TO ADMINISTER SUCH SUBSTANCES.

More than 2 million Americans are registered to legally access medical Cannabis and its products in over 40 states with the supervision of a physician.

Physician Protocols for Medical Cannabis

Physicians and health care providers have recently begun to develop clear protocols for treating patients with Cannabis-based medicines. For example, the University of California Center for Medicinal Cannabis Research (CMCR) in the U.S., completed a series of randomized clinical trials with patients and has published their guidelines for medical care[125]. Additionally, the Harvard based TheAnswerPage.org online Continuing Medical Education (CME) program offers medical Cannabis training for physicians. These guidelines suggest that Cannabis therapeutics, like any other treatment mode, should be based on careful assessment of the patient’s condition with consideration for other possible treatments. A possible treatment decision-tree for physicians, similar to those guidelines established by the Medical Board of California for doctors (using neuropathic pain as an example), is described below:
Physicians recommending medical Cannabis should:

1. Take a history and conduct a good faith examination of the patient.
2. Develop a treatment plan with objectives.
3. Provide informed consent, including discussion of side effects.
4. Periodically review the treatment's efficacy.
5. Obtain consultations, as necessary.
6. Keep proper records supporting the decision to recommend the use of medical Cannabis.

D. THE SUBSTANCE IS NOT SO RELATED IN ITS ACTION TO A SUBSTANCE ALREADY LISTED AS HAVING A POTENTIAL FOR ABUSE TO MAKE IT LIKELY THAT IT WILL HAVE THE SAME POTENTIAL FOR ABUSE AS SUCH SUBSTANCE, THUS IT IS NOT REASONABLE TO ASSUME THAT THERE MAY BE SIGNIFICANT DIVERSIONS FROM LEGITIMATE CHANNELS, SIGNIFICANT USE CONTRARY TO OR WITHOUT MEDICAL ADVICE, OR THAT IT HAS A SUBSTANTIAL CAPABILITY OF CREATING HAZARDS TO THE HEALTH OF THE USER OR TO THE SAFETY OF THE COMMUNITY.

Despite the increasing popularity of edible Cannabis products, no significant if any, diversion of existing cannabinoid drugs has ever been reported[60]. Guidelines are established for security and non-diversion of Cannabis grown in states with access programs. Dronabinol is a pure form of THC has a very low, if any, street value. And a significant black market for dronabinol may not exist, and instances of diversion are “rare and isolated” despite being available by prescription for decades[60].

FACTOR 2: SCIENTIFIC EVIDENCE OF THE PHARMACOLOGICAL EFFECTS AND GENERAL PHARMACOLOGY OF CANNABIS

We concur with the U.S. Food and Drug Administration’s (FDA) response, in specific regards, to previous FDA 8 Factor petitions to reschedule Cannabis, that there is abundant scientific data available on the neurochemistry, toxicology, and pharmacology of marijuana. However, there is limited research of actual Cannabis plant material administered in animals in modern research, most so called marijuana or Cannabis in basic or animal research is conducted with dronabinol (a Schedule III drug). Hence, if THC or dronabinol is considered to be a form of marijuana or Cannabis, as has been suggested in previous DEA and FDA 8 Factor analysis responses, then this represents another reason Cannabis should be rescheduled.

[This section includes a scientific evaluation of marijuana's neurochemistry and pharmacology, central nervous system effects including human and animal behavior, pharmacodynamics of central nervous system effects, cognitive effects, cardiovascular and autonomic effects, endocrine system effects and immunological system effects. The overview presented below relies upon the most current research.]
Basic Pharmacology

Humans have used drugs derived from plants since time immemorial. For millennia, the opium poppy (Papaver somniferum) has been utilized to lessen pain and suffering and to produce euphoria[126]. Similarly, humans have used the Cannabis plant (Cannabis spp. Sativa, Indica, or Ruderalis) for thousands of years – to reduce pain, control nausea, stimulate appetite, control anxiety, and produce feelings of euphoria[127]. While the neurochemical systems that produce the effects of opiates are separate from those responsible for Cannabis’ activity, both of these naturally occurring materials rely on a complex internal system of receptors and biochemical messengers to exert their effects on our brain and bodies. The science of a distinct “endocannabinoid” system is a relatively new discovery, which continues to reveal a remarkable number of comparatively safe therapeutic potentialities.

The first cannabinoid, cannabinol, was isolated in 1899 and its structure elucidated in 1940, but it was not until 1964 that THC [(−)-trans-Δ⁹-THC isomer], the psychotomimetically active (primary euphoriant) substance in Cannabis – was isolated, and its structure and absolute configuration determined[128-132]. The cannabinoid compounds are derived from real cannabinoid compounds in the plant, cannabinoid acids. The first one, cannabidiolic acid, was isolated and identified by Krejčí and Šantavý in 1955[131,133,134]. Since the discovery of THC, researchers have made some compelling discoveries. These discoveries help us to better understand how and why Cannabis and cannabinoid-based medicines have proven to work so well, for so many diverse maladies[135]. The evidence that these substances have the potential to be medicinally useful is overwhelming[136-139].

Some of the therapeutic benefits of the Cannabis plant are derived from the interactions of its constituent cannabinoid molecules with the human body’s own endocannabinoid system (ECS). The receptors of the ECS were discovered by Dr. William Devane in 1988[140]. After this discovery, Dr. Lumír Hanuš isolated endocannabinoids from mammalian brains[141-146]. The ECS modulates multiple and complex signaling pathways – a system responsible for regulating a variety of key physiological processes including movement, mood, memory, appetite, and pain[142].

One of the world’s leading cannabinoid researchers, Dr. Ethan Russo, offers this comprehensive description of the ECS and its importance to a variety of physiological functions:

“The analgesic and palliative effects of the cannabis and cannabinoid preparations have been amply reported over the past generation...” In essence, the effects result from a combination of receptor and non-receptor mediated mechanisms. THC and other cannabinoids exert many actions through cannabinoid receptors, G-protein coupled membrane receptors that are extremely densely represented in central, spinal, and peripheral nociceptive pathways. Endogenous cannabinoids (endocannabinoids) even regulate integrative pain structures such as the periaqueductal gray matter. The endocannabinoid system also interacts in numerous ways with the endogenous opioid and vanilloid systems that can modulate analgesia, and with a myriad of other
neurotransmitter systems such as the serotonergic, dopaminergic, glutamatergic, etc., pertinent to pain. Research has shown that the addition of cannabinoid agonists to opiates enhances analgesic efficacy markedly in experimental animals, helps diminish the likelihood of the development of opiate tolerance, and prevents opiate withdrawal. Researchers have suggested that a clinical endocannabinoid deficiency may underlie the pathogenesis of migraine, fibromyalgia, idiopathic bowel syndrome, and numerous other painful conditions that defy modern pathophysiological explanation and lack adequate treatment[147].”

More than 20 years since researchers began developing an understanding of the ECS, two types of cannabinoid receptors – CB1 and CB2 – have been identified, setting the stage for discoveries that have dramatically increased our understanding of how Cannabis and its many constituent cannabinoids affect the human body[148,149]. CB1 receptors are found predominantly in the central nervous system, particularly in the brain, and in organs and tissues such as the eyes, lungs, kidneys, liver, and digestive tract[66]. The brain’s receptors for cannabinoids far outnumber the presence of all other neurotransmitter receptors combined. The relative safety of Cannabis is, at least in part, explained by the fact that these otherwise numerous cannabinoid receptors are virtually absent from those regions of the brainstem responsible for vital functions such as breathing and heart control. In comparison, CB2 receptors are primarily located in tissues associated with immune function, including the spleen, thymus, tonsils, bone marrow, and white blood cells[66]. Cannabis compounds such as CBD also interact with non-cannabinoid serotonin (i.e., 5HT1A) and adenosine (i.e., A2A) receptors[67,78,150-154]. There are a number of orphan receptors that are recognized as novel therapeutic targets that also appear to play a role in Cannabis pharmacology[155-159].

Ongoing research is helping scientists and physicians to increasingly understand the crucial role of the ECS in regulating a variety of key bodily functions. As best noted by the researcher who first isolated and identified THC – Dr. Raphael Mechoulam – the discovery of the ECS has generated a great deal of interest in identifying opportunities for the development of a wide variety of Cannabis-based and synthetic cannabinoidergic therapeutic drugs[160-162].

**Central Nervous System Effects**

THC increases the metabolic rate in the brains of humans and other mammals[163]. Most cannabinoid effects are mediated by cannabinoid receptors, their distribution reflects many of the medical benefits and side effects in this eight-factor analysis. To name a few, cannabinoids can have analgesics effects, muscle relaxant effects, enhance appetite, and hormonal actions. Neuroprotective properties of different cannabinoids (i.e., THC and CBD in ischemia and hypoxia are examples of some well-known receptor-independent actions of cannabinoids.

Cannabinoids interact with a number of neurotransmitters and neuromodulators, such as acetylcholine, dopamine, gamma-aminobutyric acid (GABA), histamine, serotonin, glutamate, norepinephrine, prostaglandins and the endorphin (opiate) system. A number of pharmacological effects of Cannabis can be explained on the basis of such interactions. For example:
• Tachycardia and hypo-salivation with dry mouth are mediated by the effects of THC on acetylcholine activity[164,165].
• Anti-emetic properties are due, in part, to interactions with serotonin[166,167].
• Hypomotility and sedation from Cannabis are in part due to interactions involving acetylcholine, GABA, and prostaglandins.
• Therapeutic effects in movement and spastic disorders are due to interactions involving GABAergic, glutamergic, and dopaminergic transmitter systems[126]

Human Behavioral Effects

In many species a mixture of depressant and stimulant effects in the CNS characterizes the behavioral effects of THC. In humans, THC intoxication is usually noted as a pleasant and relaxing experience[168]. Occasionally, unpleasant feelings are reported such as anxiety, which may escalate to a panic attack. A sense of enhanced well-being may alternate with dysphoric phases. Cannabis improves taste responsiveness and enhances the sensory appeal of food[169]. Cannabis or THC may induce sleep.

Adverse effects of medical Cannabis are within the range of effects tolerated for other medications[170,171]. It is has never been convincingly demonstrated that heavy Cannabis use impairs cognition outside of acute intoxication. Long-term medical Cannabis use is reported to be well-tolerated without significant physical or cognitive impairment[40,47,52,57,172]. Acute THC intoxication impairs learning and memory, and can adversely affect psychomotor and cognitive performance. Neuropsychological performance can be impaired from intoxication but after cessation of use these effects are normalized without signs of residual behavioral effects[40].

Cardiovascular

Historically Cannabis has been used as a treatment for a number of ailments such as atherosclerosis, cardiac palpitations, and hypertension[173]. This suggests the involvement of the cardiovascular (CV) system, and since the 1970’s the effect of Cannabis and the cannabinoids on the CV system has been studied intensively[21,174-176].

In vivo THC can cause a decrease in blood pressure and heart rate in anesthetized mammals, and an increase in blood pressure and decrease in heart rate in conscious animals. In humans there is an acute increase in heart rate, but variable effects on blood pressure. The effects of THC are largely through the CB₁ receptors, which mediate the activity of the autonomic nervous system.

In vitro observations have documented that vasorelaxation can be caused by the phytocannabinoids THC, CBD, CBN, and THCV and vasoconstriction can be caused by THC and THCV[177-184]. Vasorelaxation by THC is mediated by prostaglandins, activation of sensory nerves, ion channel modulation, and activation of PPAR-gamma. Vasoconstriction from THC is mediated by prostanoids, CB₁ receptors, and sympathetic
stimulation; THC can inhibit the vasorelaxation caused by sensory nerve activation from acetylcholine, bradykinin, and anandamide. One study in human arteries suggests that CBD may cause vasorelaxation by activating TRPV1, nitric oxide, and allosterically modulating CB1 receptors[181].

A 2016 study on the cardiovascular effects from the abrupt cessation of long-term Cannabis use in humans showed no significant changes between groups[185]. The authors conclude, “In the presented post-hoc analysis, no significant changes in heart rate, blood and pulse pressure were found after abrupt cessation of long-term daily cannabis smoking, which stands in contrast especially to the results of the study of Vandrey et al., who found significant increases in blood pressure and slight increases in the heart rate of their sample[185].”

Respiratory

Unlike opiates, Cannabis compounds, such as THC, do not depress respiration and cannot depress respiratory drive due to sparse receptor density in medullary respiratory centers of the human brain[34,35]. Pulmonary issues associated with Cannabis smoking include chronic bronchitis, particularly chronic cough, and sputum production, with more variable effects on wheezing and generally negative effects on breathlessness. Reducing Cannabis use often leads to a resolution of these symptoms. Reducing or quitting Cannabis smoking was associated with reductions in the prevalence of cough, sputum and wheeze to levels similar to nonusers[186]. However, these issues are avoidable by using vaporizer/volatilizer technology or alternative routes of administration[79,80]. Importantly, lifetime use of Cannabis smoking is not associated with an increase incidence of lung cancer[81].

Cannabis has been documented to treat symptoms of certain airway ailments such as asthma. Bronchodilatory effects of orally administered dronabinol were not found in asthmatic patients although such effects of inhaled THC had been shown[187-189]. For example, a case report from Costa Rica documents the study of two children with asthma, one treated the ailment by smoking Cannabis, while the other child abstained and succumbed to the disease[44].

Endocrine Systems

The earliest systematic studies of Cannabis and the compounds found on the plant, focused on the effects on mood, anxiety, and the endocrine system[190]. The effects of Cannabis on mood and anxiety disorders have already been covered earlier in this document, this section will focus on the effects of Cannabis and related compounds on endocrine systems known to be stress responsive and otherwise contribute to mood and related disorders.

The dysfunction of the hypothalamic-pituitary-adrenal (HPA) axis is common etiology or underlying mechanism in humans with major depression[191]. Conceptually the hyperactivity of the HPA axis
accompanied by depression, hence attenuating hyperactivity of the HPA axis is a common feature of targeted therapies for related depression and mood disorders. The inability to control or suppress the release of cortisol is a considered diagnostic of mood disorders related to the HPA axis.

In naïve or infrequent users, Cannabis or THC can increase the secretion of cortisol, while regular or chronic Cannabis users demonstrated an attenuation of this effect, perhaps representing the development of tolerance[192,193]. Additionally, clinical research has confirmed an inhibition of stress-induced activity of the HPA axis in adult and adolescent Cannabis users[194,195]. CBD has been demonstrated to stimulate the HPA axis, attenuating the diurnal decline in cortisol levels[196].

Preclinical and basic research of the effects of cannabinoids on the HPA axis has demonstrated that the work in mammalian species parallels the effects in humans. To summarize the animal and human research, the data demonstrate that Cannabis and cannabinoids can increase HPA axis activity via the monoaminergic hindbrain nuclei, while the inhibitory effects on cortisol (stress hormone) secretion is due to direct actions on limbic and hypothalamic circuitry.

Research has investigated the effects of Cannabis on the hypothalamic-pituitary-thyroid (HPT) axis. Disorders of the HPT axis are associated with depressed mood in adults and cognitive deficits acquired during development. In humans who regularly use Cannabis found that thyroid hormones vital for proper development and metabolic regulation, were within normal limits and did not correlate with concentrations of THC or its major metabolites[197].

Growth hormone, or somatotropin, is an anabolic hormone that stimulates growth and regulates energy homeostasis. Prolonged and heavy administration of more than 200mg of THC a day in human males can decrease serum growth hormone concentrations that are evoked by insulin (a gold standard test for growth hormone activity) [198]. The effects of smaller doses of THC have not been reported to have significant effects on growth hormone release. This suppression of growth hormone release has not been reported in any clinical trial of Cannabis or its products.

The pineal gland synthesizes melatonin during the night and plays an important role in the sleep wake cycle in mammals. A study of THC on melatonin secretion in human subjects found that 10mg of THC administered by smoking when melatonin concentrations low, can produce a 30-fold increase in melatonin 1-2 hours post smoking[199]. However, in the same study one of subjects had very high basal melatonin level and THC administration reduced the concentration of melatonin in this individual. Increases in melatonin concentrations, such as those that are often observed hours after Cannabis use, contribute to sleep.

The effects of the phytocannabinoids on the HPA axis and reproductive hormones are well described in human and preclinical studies. More of research is needed in the areas of growth hormone and melatonin in light of findings that cannabinoids can beneficially alter the activity of these hormones.
### Immune System

THC and CBD converge to inhibit immune functional activities by altering the production of pro-inflammatory cytokines and chemokines. The common mode of action between THC and CBD causes a switch from the production of Th1 cytokines such as IFN-gamma, TNF-alpha, IL1Beta, and IL-2 to that of Th2 cytokines such as IL-10 and IL-4[200,201]. THC and CBD have anti-inflammatory effects and can beneficially inhibit the migration of immune cells[201-204]. THC, CBD, and Cannabis have a documented ability to alter the functioning of the immune system but a role in increasing susceptibility to infection and/or disease progression in humans has failed to reach a significant association in many studies[174,205-207].

### Factor 3: The State of Current Scientific Knowledge Regarding the Drug or Other Substance

#### Chemistry

Cannabinoids are a class or group of related compounds consisting of more than a hundred terpenophenolic compounds (currently 144 have been documented), most commonly associated with the pharmacological activity of Cannabis. Cannabinoids mainly exist in the Cannabis plant as carboxylic acids and are converted to neutral analogs by light and heat while in storage or when combusted[208]. The alkyl group at the third carbon atom is considered an important site in substrate-receptor interactions[208,209]. This group is typically a pentyl – for example, in Δ9-tetrahydrocannabinol (Δ9-THC), cannabigerol (CBG), cannabidiol (CBD), and cannabinol (CBN) – but can also be a propyl, in which case the compounds are named by attaching the suffix -varin to the name of the pentylated analog, e.g., tetrahydrocannabivarin (THCV), cannabidivarin (CBDV), cannabigerovarin (CBGV), and cannabivarin (CBNV) – butyl (THC-C4, CBD-C4, and CBN-C4) or methyl (tetrahydrocannabiorcol, cannabidiorcol, and cannabiorcol).

Cannabis plants typically exhibit one of the three main distinctly different chemotypes based on the absolute and relative concentrations of Δ9-THCA, CBD, and CBN (after conversion from the respective acids). Some researchers refer to these as THC or drug-type, intermediate type, and fiber-type[21,210]. Plants with more rare chemical profiles have been established, including those predominant in CBG or THCV, and those lacking any cannabinoids, for a total of five general types[211,212]. The mean content of Δ9-THC, (including Δ9-tetrahydrocannabinolic acid [Δ9-THCA]), in the THCA-predominant plant material has been increasing in the past few decades, due to changes in cultivation techniques and selective breeding.

The cannabinoid profile is affected most by the plant’s sex, genotype, and maturity followed by environmental and other factors, such as light intensity, light cycle, temperature, and fertilization[213,214]. Cannabinoids are produced in glandular trichomes distributed across all epidermal surfaces of the plant’s aerial parts at varying degrees. The distribution of glandular trichomes and, hence, phytocannabinoids varies widely, from the lowest concentrations found in stems to increasing amounts in...
Cannabis is a plant that has been used for its psychoactive properties for thousands of years. It is known for its ability to alter perception, mood, and consciousness. The psychoactive component of cannabis is THC (delta-9-tetrahydrocannabinol). THC is a lipophilic compound that permeates cell membranes and can cross the blood-brain barrier both when inhaled (i.e., vaporized or smoked) and ingested.

**Human Pharmacokinetics**

The best-studied pharmacokinetics of a substance from *Cannabis* is THC[215]. The pharmacokinetic profiles of CBD and CBN are somewhat similar to that of THC. No significant differences in the pharmacokinetics of women and men have been found. Values for clearance average about 0.2 L/kg-hr, but are highly variable due to the complexity of cannabinoid distribution.

**Metabolism**

The metabolism of THC is complex, the route of administration affects the quantitative profile of metabolites, and this is well studied in a number of different species[216-220]. The inter-species differences may in part be responsible for some problems of extrapolating of pharmacological and toxicological data.

More than 100 metabolites for THC have been identified, including di- and tri- hydroxy, ketone, aldehyde, and carboxylic acid THC metabolites. THC metabolizes primarily to 11-OH-THC, THCCOOH and associated glucuronide conjugates. The liver is the primary site of cannabinoid metabolism, and to a much lesser extent the brain, intestine, and lung are other tissues metabolize phytocannabinoids[221-223].

11-OH-THC is a potent, primary metabolite that is produced by the C9 hydroxylation of THC by liver/hepatic cytochrome P450,2C9, 2C19, and 3A4 enzymes. Early literature on the subject originally proposed that 11-OH-THC was the main psychoactive analyte. 11-OH-THC is produced in equal amounts to orally administered THC, but only about 10% of THC is metabolized in this way when inhaled. 11-OH-THC conjugates with fatty acids are proposed to be the main form of THC storage within tissue[224].

The concentrations THCCOOH rise above that of THC in the plasma about 30 minutes after inhalation and about 1 hour after oral administration. THCCOOH-glucuronide is a more water-soluble metabolite, it is readily excreted, the major metabolite in blood and plasma, can be detected in the blood for many hours and is considered to be the principal Phase II metabolite[225-227].

THC metabolizes to equipotent 11-hydroxy-THC (11-OH-THC) and inactive 11-nor-9- carboxy-THC (THCCOOH) metabolites during Cannabis smoking. “For inhalation, peak concentrations for THC were observed 8 minutes (range 6–10 minutes) after 1st inhalation, whereas 11-OH-THC peaked at 15 minutes (range 9–23 minutes) and THC-COOH at 81 minutes (range 32–133 minutes)[228].” The ratio of THC to 11-OH-THC declines and reaches a 2:1 ratio around 2-3 hours.
After oral administration, much higher amounts of 11-OH-THC are formed than with inhalation or intravenous administration[229-232]. In several clinical studies the plasma levels of 11-OH-THC exceed THC concentrations after oral administration[175,232-234].

Many metabolites of CBD have been discovered but the two primary metabolites are 7-OH-CBD and 7-oic acid[235,236]. The 7-oic acid and its hydroxylated derivatives are abundant in human urine and feces[216].

The primary metabolite of CBN is monohydroxy CBN, with 7-OH metabolite being the most abundant in the milieu[220,235,237-239]. The metabolic profile of CBD is less complex than that of THC or CBD.

A significant first pass liver effect occurs only with oral administration.

### Distribution

Plasma THC levels rapidly decrease as this highly lipophilic compound is easily distributed through vascular tissue and metabolized in the liver[240]. Shortly after administration significant concentrations of cannabinoids are found in sites such as body fat (long-term storage), liver, heart, lung, gut, kidney, spleen, mammary gland, placenta, adrenal cortex, thyroid, and pituitary gland.

### Excretion

Eighty percent of THC is excreted through feces. Only traces are secreted through urine. The dominant urinary metabolite is THC-COOH-O-glucuronide, 50% is excreted within the first day after administration.

CBD shows a similar excretion profile with acids and glucuronide conjugates dominating the profile.

A single dose of CBN was excreted in urine within 72 hours.

### Absorption and Bioavailability

In this sections below, various routes of absorption and bioavailability are reviewed.

### Inhalation

A rapid absorption occurs after the inhalation of smoked or vaporized Cannabis[168]. THC can be detected in plasma within seconds after the first inhalation but absorption from the lungs reaches peak concentrations in about 3-8 minutes. It is estimated that between 15-50% of the cannabinoids, such as
THC, reach systemic circulation due to: loss by pyrolysis (30%), loss to side stream smoke (10-30%), and incomplete absorption and metabolism in the lung. Bioavailability also depends on inhalation topography, such as the depth of inhalation, duration of inhalation, and length of holding the inhalation in the lungs. Generally, the bioavailability of inhaled THC is considered to be approximately 25%, with large intra- and inter-subject variability due to many factors including inhalation topography[241,242]. The bioavailability of THC is much greater than that from oral administration.

A systemic bioavailability for the inhalation of THC can be greater for participants of clinical studies that have previous experience with Cannabis. In one study regular Cannabis users demonstrated a bioavailability of THC of 23 +/−16% vs 10 +/−7% for occasional users[243]. Similarly, another study found the bioavailability of inhaled THC to be 27 +/−10% for the regular users and 14 +/−1% for the light or occasional users[244]. This data also suggests that through inhalation, experienced users can titrate their dose.

Bioavailability of inhaled CBD is 31 +/−13% and for CBN this approximately is 38%. CBD and CBN are often not detected 1 hour after inhaled administration, detection of CBD and CBN may be an indicator of recent use[225].

More efficient Cannabis inhalation delivery systems are being developed. Medical devices such as vaporizers have demonstrated to be more efficient, reducing side stream smoke, reducing production of harmful by-products related to combustion, and are also associated with avoiding any harmful effects related to smoking (i.e., bronchitis and airway irritation)[245-247].

After 16 and 30 mg inhaled THC, plasma concentrations reached 7.0 ± 8.1 and 18.1 ± 12.0 micrograms/L following one inhalation with mean (range) or maximal concentration of 84.3 (range 50–129) and 162.2 micrograms/L (76–267), respectively[248].

Plasma THC concentrations remain greater than 1 ug/L for at least 1 day after cessation of either daily Cannabis smoking or multiple oral THC doses.

**Oral Administration**

Oral administration of pure THC is slow, unpredictable and erratic; absorption is lower with delayed peak concentrations, and in some individuals two (and possibly more) THC metabolite peaks appear over time[168,249-252]. These two peak THC concentrations that appear after ingestion are possibly due to enterohepatic recirculation. Systemic bioavailability of dronabinol (marketed as Marinol) was only 10% as measured as a result of the extensive first-pass liver metabolism. Generally, maximal plasma concentrations can be reached 60-120 minutes after administration. However, in several studies peak plasma concentrations were observed as late as 4 to 6 hours after administration[168,230,253].

Absorption from oral administration is affected by the dose, vehicle (i.e., administering THC in sesame oil improves bioavailability), and physiological factors such as metabolism and excretion rates, ultimately influencing drug concentrations.
An extensive first-pass liver metabolism further reduces the oral availability of THC and other cannabinoids. THC is metabolized before it reaches the sites of action when taken orally. For example, 20mg of THC in food (chocolate cookie) and administration of dronabinol resulted in very low bioavailability after 1-5 hours, of 6 +/-3% or 7+/−3%, respectively. Peak plasma concentrations for the THC in food were reported as 4.4-11ug/L 1-5 hours about ingestion. Plasma THC concentrations remain greater than 1 ug/L for at least 1 day after cessation of either daily Cannabis smoking or multiple oral THC doses.

There are also high inter-individual variations with cannabinoid metabolism.

**Ophthalmic Administration**

An ophthalmic administration study in animals demonstrated a bioavailability of THC, formulated with mineral oil, to vary between 6-40%[254]. Peak plasma concentration were reached after 1 hour and remained at significant levels for hours.

**Sublingual Administration**

*Cannabis* extracts can be administered sublingually, absorbed through the muscosa, to avoid first-pass metabolism by the liver. This results in low plasma levels of THC and CBD metabolites compared to inhalation, which resembles oral administration’s pharmacokinetic profile.

**Dermal Administration**

The permeability of THC must be increased to result in significant concentration in the blood of mammals. In rats, a stable THC isomer was formulated with water, oleic acid, propylene glycol, and ethanol[255,256]. Studies examining or developing transdermal delivery of cannabinoids have found the mean effective permeability of coefficient for THC (in propylene glycol) of 6.3 x 10^-6 cm/hour[168].

**Rectal Administration**

Rectal formulations absorption is lower but more consistent than oral formulation. The THC ester (hemisuccinate) suppositories demonstrated a bioavailability of 50%[229].

**Plasma Levels vs. Administration Routes**

Plasma profiles are similar for inhalation and injection while oral and sublingual administration share similar pharmacokinetic profiles. THC plasma maxima in the range of 100-250 ng/ml are measured after smoking 1gram of *Cannabis* with 1.75% and 3.25% THC. These plasma levels are significantly lower for sublingual administration.
Medical Uses for Marijuana/Cannabis

There is a wealth of clinical information available on the uses of standardized medical Cannabis products. The FDA has approved new drug applications for Cannabis. For example, a CBD-rich extract (Marketed as Epidiolex) is an imported, purified Cannabis extract that has been approved for clinical use in children and is currently in clinical practice across several institutions in the U.S. Additionally, an inhaled Cannabis study has recently been approved for investigating therapeutic effects in PTSD. At the time of writing this document, according to clinicaltrials.gov, there are hundreds of approved human research studies. These studies are currently either completed, recruiting, approved, or in process. A total of 144 are approved for THC, 96 are approved for CBD, and 559 are approved for marijuana or Cannabis. Due to Schedule I status, medical Cannabis preparations such as nabiximols and CBD-rich extracts are imported and cannot be manufactured in the U.S., even though they are licensed pharmaceutical products.

Whereas research in the U.S. has been historically restricted by a prevailing Federal prohibition on Cannabis and cannabinoids in the past, recent global discoveries have driven interest amongst scientists to investigate the now more than 100 different cannabinoids thus far identified on the Cannabis plant. Entire organizations have emerged, dedicated to basic medical and clinical research on the cannabinoid molecules. The International Cannabinoid Research Society (ICRS), formally incorporated as a scientific research organization in 1991, holds an annual international research symposium, and since its inception, the membership has more than quadrupled (www.icrs.co). The International Association for Cannabinoids as Medicine (IACM), founded in 2000, publishes a bi-weekly newsletter and holds a biennial symposium to highlight emerging clinical research concerning Cannabis therapeutics (www.cannabis-med.org). The University of California established the Center for Medical Cannabis Research (CMCR) in 2001 to conduct scientific studies to ascertain the general medical safety and efficacy of Cannabis products.

In 2010, the CMCR issued a report on the 14 clinical studies it has conducted, most of which were FDA-approved, double-blind, placebo-controlled clinical studies that demonstrated that Cannabis can control pain – in some cases better than all available alternatives[125]. More recently, the International Cannabis and Cannabinoid Institute (ICCI) was founded in the Czech Republic[257]. The goal of ICCI will be to identify, coordinate, and support global research priorities for the advancement of Cannabis and cannabinoid treatments through a multidisciplinary evidence-based approach that incorporates innovative tools and approaches (www.icci.science). Each of these international research organizations is dedicated, at least in part, to properly controlled, methodological scientific exploration into the therapeutic potential of Cannabis and the cannabinoids.

Emerging Clinical Data

To date, more than 30,000 modern peer-reviewed scientific articles on the chemistry and pharmacology of Cannabis and the cannabinoids have been published, and more than 1,500 articles investigating the body’s natural endocannabinoids are published every year. In recent years, modern gold-standard placebo-controlled human trials have also been conducted.
A 2009 review of clinical studies conducted over a 38-year period found that “nearly all of the 33 published controlled clinical trials conducted in the U.S. have shown significant and measurable benefits in subjects receiving the treatment[148].” The review's authors made particular effort to note that cannabinoids have the capacity for analgesia through neuromodulation in ascending and descending pain pathways, neuroprotection, and by anti-inflammatory mechanisms – all of which indicate that the cannabinoids found in Cannabis have applications in significantly managing chronic pain, muscle spasticity, cachexia, and other variously debilitating conditions.

Currently, Cannabis is most often recommended as a complementary or adjunctive medicine. However, there exists a substantial consensus amongst experts in the relevant disciplines – including the American College of Physicians – that Cannabis and cannabinoid-based medicines have undeniable therapeutic properties that could potentially treat a variety of serious and chronic illnesses. What follows is a brief, annotated compilation of the emerging clinical data in support of the therapeutic usefulness of the cannabinoids.

Cancer

Cancer patients undergoing radiation and/or chemotherapy often suffer from significant nausea, pain, and other unpleasant side effects of their treatment. The effects of oral THC and mixed cannabinoid administration has been studied in more than 35 clinical trials for the treatment of chemotherapy-induced nausea and vomiting, and more than 40 clinical studies have looked at appetite modulation by cannabinoids. Years before any U.S. State authorized the medical use of Cannabis, a 1991 Harvard Medical School study revealed that nearly half (44%) of U.S. oncologists were recommending Cannabis to their patients as a way of mitigating side effects associated with cancer treatment[258].

In its 1999 review, the Institute of Medicine (IOM) concluded that Cannabis could be a valid, safe medicinal alternative for many people living with cancer[259]. Specifically, the IOM notes state, “In patients already experiencing severe nausea or vomiting, pills are generally ineffective, because of the difficulty in swallowing or keeping a pill down, and slow onset of the drug effect[260].” Cannabinoid medicines are both safely, and somewhat easily, formulated into both inhaled and suppository formats.

Since the release of the IOM report, new research has been published which clearly supports the use of Cannabis and the cannabinoids to curb the debilitating effects of cancer treatments. In 2001, a review of clinical studies of individuals with cancer, conducted in several U.S. states spanning multiple decades, revealed that inhaled cannabinoids and oral cannabinoids (in 591 and 1,281 subjects, respectively) were significantly effective anti-emetics versus the nausea and vomiting of chemotherapy[261]. Other studies have come to similar conclusions – that the active components in Cannabis produce palliative effects in cancer patients by preventing nausea, vomiting, and pain while stimulating appetite.

Beyond these palliative effects, the tumor-fighting properties of the cannabinoids have also been demonstrated in numerous pre-clinical studies, withstanding a successful Phase I clinical study looking at the safety of THC in patients with recurrent brain cancer. Researchers have observed that “these compounds [are] shown to inhibit the growth of tumor cells in culture and animal models by modulating key cell-signaling pathways. Cannabinoids are usually well tolerated, and do not produce the generalized
Combating Nausea and Vomiting Induced by Chemotherapy

*Cannabis* is used most often to combat the nausea and vomiting induced by chemotherapeutic agents, as well as pain caused by various cancers. More than 35 human clinical trials have sought to examine the effects of phytocannabinoids or synthetic cannabinoids on nausea, including several U.S. state-sponsored trials that took place between 1978 and 1986[258,263]. In reviewing this literature, scientists have concluded that, “THC is superior to placebo, and equivalent in effectiveness to other widely-used anti-emetic drugs, in its capacity to reduce the nausea and vomiting caused by some chemotherapy regimens in some cancer patients[263].”

A 1998 review by the British House of Lords Science & Technology Select Committee concluded, “cannabinoids are undoubtedly effective as antiemetic agents in vomiting induced by anti-cancer drugs. Some users of both find *Cannabis* itself more effective[264].” The House of Lords review was built upon data provided in a 1997 inquiry by the British Medical Association that further determined that natural *Cannabis* is, in some cases, more effective than synthetic THC (i.e. dronabinol)[265].

Previous clinical work has shown that orally administered synthetic cannabinoids (nabilone and dronabinol) are superior to dopamine receptor antagonists in preventing chemotherapy-induced nausea and vomiting. Until recently, there was not adequate information available on the tolerability of an acute dose titration of a standardized whole-plant *Cannabis* medicine; the results of clinical work suggest that rapid titration of a standardized *Cannabis* medicine appears to be well tolerated by most patients and efficacious in reducing the incidence of delayed nausea and vomiting[175,266].

Antineoplastic Actions of Cannabinoids

Recent scientific advances in the study of the endocannabinoid system have yielded exciting new leads for potentially groundbreaking anti-cancer treatments. In the past decade, preclinical studies, conducted both *in vivo* and *in vitro*, have demonstrated that different cannabinoids might have a remarkable effect in fighting different types of cancer cells. To date, studies have shown that cannabinoids arrest many kinds of cancer growths, both through the promotion of apoptosis (a.k.a. programmed cell death) and by arresting angiogenesis (blocking increased blood vessel production). Cannabinoids have also been shown to halt the proliferation, or spread, of cancer cells in a wide variety of cancer types. Unlike conventional chemotherapy treatments – that work by creating a toxic environment in the body, and are frequently responsible for compromising overall health – cannabinoids have been shown to selectively target tumor cells, leaving healthy surrounding cells undisturbed.

Cannabinoids and Tumor Reduction

The direct anti-tumor and anti-proliferation activity of cannabinoids, specifically CB\(_1\) and CB\(_2\) agonists, have been demonstrated in dozens of studies across a range of cancer types, including brain (gliomas), breast, liver, leukemic, melanoma, pheochromocytoma, cervical, pituitary, prostate, and bowel[262,267-285]. Evidenced anti-tumor activity has led to regression of tumors, reductions in both toxic effects of conventional chemotherapies[262].”
vascularization (blood supply) and metastases (secondary tumors), as well as the direct destruction of cancer cells (apoptosis) in laboratory animals and in vitro human tissues[286-289]. A 2009 review of recent studies on the role of cannabinoids and cannabinoid receptors in the treatment of breast cancer notes that research on the complex interactions of endogenous cannabinoids and receptors is leading to greater scientific understanding of the basic mechanisms by which all cancers develop[268,287].

Cannabinoids have been shown to inhibit tumor growth in laboratory animals in multiple studies [268,290,291]. In one study, injections of synthetic THC eradicated malignant brain tumors in one-third of treated rats, and prolonged lifespan in another third by as long as six weeks. Other research on pituitary cancers suggests that cannabinoids may be the key to regulating human pituitary hormone secretion [292,293].

Research published in 2009 found that the non-intoxicating cannabinoid, CBD, inhibits the invasion of both human cervical cancer and human lung cancer cells. By manipulating CBD’s up-regulation of a tissue inhibitor, researchers may have revealed the mechanism behind CBD’s tumor-fighting effects[294]. A further in vivo study demonstrated “a significant inhibition” of lung cancer metastasis in mice treated with CBD[295]. The mechanism of the anti-cancer activity of CBD and other cannabinoids has been repeatedly demonstrated in both breast and brain cancers[296-299].

The anti-tumor effects of the cannabinoid THC on cholangiocarcinoma cells, an often-fatal type of cancer that attacks the liver’s bile ducts, has also been evidenced. A 2009 study found that “THC inhibited cell proliferation, migration and invasion, and induced cell apoptosis.” Interestingly, at low concentrations, THC reduced both the migration and invasion of cancer cells, while at high concentrations, THC triggered cell-death in tumors. In short, THC both reduced the activity and the number of cancer cells[281].

Research on cannabinoids and gliomas – a type of aggressive brain cancer for which there is no known cure – holds true promise for future treatments of this devastating disease. A study that examined both animal and human glioblastoma multiforme (GBM) tumors, the most common and aggressive form of brain cancer, describes how cannabinoids minimize glial growth by regulating the blood vessels that supply the tumors[300]. In another study, researchers demonstrated that the administration of CBD significantly inhibits the growth of subcutaneously-implanted 87 human glioma cells in mice[294]. The authors of the study noted that CBD alone was capable of producing a significant antitumor effect, both in vitro and in vivo, thus suggesting a possible application of CBD as a viable antineoplastic agent in humans.

The targeted effects of cannabinoids on GBM were further demonstrated in 2005 by researchers who showed that the cannabinoid THC both selectively inhibited the proliferation of malignant cells and induced them to die off, while leaving healthy cells unaffected [25]. While CBD and THC have each been demonstrated to possess tumor-fighting properties in isolation, research published in 2010 shows that the molecules work better in combination, as CBD enhances the inhibitory effects of THC on GBM cell proliferation and survival[301]. More recent work in mice has confirmed this enhancing effect of CBD on THC in cancer cells in animals. The research also tested a THC/CBD combination with and without chemotherapy in the animals. The research showed that combinations of Cannabis compounds can significantly improve the effect of the chemotherapy agent temozolomide[291].
Similarly, researchers have demonstrated in the last few years the mechanism by which cannabinoid and cannabinoid-like receptors in brain cells regulate these cells' differentiation, functions, and viability. This is suggestive evidence that cannabinoids – and other drugs that target cannabinoid receptors – might manage neuroinflammation and thus eradicate malignant astrocytomas, a type of cancer [268,302-304]. Such recent studies confirm the positive findings of earlier studies indicating the effectiveness of cannabinoids in fighting gliomas, some of the deadliest known forms of brain cancer[267,305-307].

The potential of cannabinoids to fight cancer in humans has also been seen in three recent large-scale population studies. These studies were originally designed to find correlations between smoked Cannabis and cancers of the lung, throat, head, and neck. Rather, researchers discovered that the cancer rates of Cannabis smokers were, at worst, seen in no greater prevalence than in those that smoked nothing at all – and many fared significantly better[81]. Results of this study suggested that cannabinoids might actually have a prophylactic effect against cancer development, as seen in the anti-proliferative effect now demonstrated both in vitro and in vivo[308]. Lastly, a case report that highlights the spontaneous regression of brain cancers in two teenagers, was associated with current medical Cannabis use[309].

**HIV/AIDS**

Cannabis has proven effective in improving the quality of lives of many individuals living with human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS). Cannabinoid-based medicine is useful for the syndrome of HIV’s effects – to help manage appetite loss, wasting, nausea, vomiting, pain, anxiety, stress, depression, and other concomitant symptoms associated with both the disease and the anti-retroviral regimen used to treat it. As many as one in four people living with HIV/AIDS use Cannabis for medical purposes in the U.S.[310].

An international group of nursing researchers determined from a longitudinal, multi-country, multi-site, randomized-control clinical trial that Cannabis is frequently used to manage the six common symptoms of HIV/AIDS. A 2009 study found that a significant percentage of those with HIV/AIDS find Cannabis to be efficacious for treating their anxiety, depression, fatigue, diarrhea, nausea, and peripheral neuropathies. Researchers noted that “those who did use marijuana rate it as effective as prescribed or over the counter medicines for the majority of common symptoms...[311].”

In addition to the debilitating symptoms of the disease itself, Cannabis has proven to be effective in controlling the unpleasant effects of the drugs used to treat HIV/AIDS. According to a 2007 study, people living with HIV/AIDS who use Cannabis to combat the side-effects of the Highly Active Antiretroviral Therapy (HAART therapy) are approximately three times more likely to remain on their prescribed drug therapies than those who do not use Cannabis[312].

In the 1970s, a series of human clinical trials established that Cannabis can stimulate food intake and thus, can cause weight gain in healthy volunteers – a finding confirmed by numerous subsequent studies. In a randomized trial in people living with AIDS, THC was seen to both significantly improve appetite and decrease nausea, in comparison to the effects of placebo administration. There were also trends towards both improved mood and weight gain. Unwanted effects – e.g. dry mouth, drowsiness and anxiety – were of generally mild or moderate intensity, and were proven to be of little consequence to the...
user[205,313,314]. The IOM’s comprehensive review in Marijuana and Medicine concluded, “For patients such as those with AIDS or who are undergoing chemotherapy and who suffer simultaneously from severe pain, nausea, and appetite loss, cannabinoid drugs might offer broad-spectrum relief not found in any other single medication.”

To address concerns involving Cannabis-based medicines decreasing treatment efficacy, an FDA-approved preliminary safety trial of smoked Cannabis, conducted in 2003 at the University of California, San Francisco, concluded that neither synthetic THC nor inhaled Cannabis had any significant effect on the immune system or viral load. Moreover, the researchers noted that those study participants who used Cannabis gained weight[205].

In addition to the overall safety demonstrated in these trials, cannabinoids may also inhibit the spread of the HIV virus within the human body by acting directly on CD4+ T cells – T cells are critical to immune function and are a target of the HIV virus. A 2012 study found that a cannabinoid activating CB2 receptors selectively produced a dose-specific reduction of HIV infection by up to 50%[311,315-317]. This study suggests that therapeutic use of cannabinoids might help to fight the spread of the HIV virus to uninfected T cells in the late stages of HIV-1 infection[318]. Previous research has shown that the use of cannabinoid drugs in patients with HIV is associated with an increase in CD4+ T cell number and has been shown to reduce viral load in an animal model of HIV.

**Neuropathic Pain**

The effectiveness of Cannabis and cannabinoids in managing pain has been demonstrated in more than three dozen preclinical and clinical trials, comprising more than 6,000 patient-years of data as of 2012[126]. A 2009 review noted simply: “a large number of research articles have demonstrated the efficacy of cannabinoids...[and so] cannabinoids show promise for treatment of neuropathic pain[318].”

More than one-third of people living with HIV/AIDS suffer from excruciating nerve pain in the hands or feet, frequently in response to the antiretroviral therapies that constitute first-line treatment for HIV/AIDS. This induced neuropathic pain is extremely difficult to treat and, as a result, many individuals reduce or discontinue their HIV/AIDS therapies.

A series of clinical studies of HIV/AIDS patients demonstrated that cannabinoids can significantly reduce neuropathic pain and promote weight gain, without compromising the immune system[319-321]. Research conducted by the University of California, San Francisco involving a randomized, placebo-controlled clinical trial of 50 people who had experienced neuropathic pain for a group average of six years, showed that smoked Cannabis was both well-tolerated and proved to effectively relieve chronic neuropathic pain from HIV-associated sensory neuropathies[321]. Other double-blind, placebo-controlled clinical trials with people living with HIV neuropathic pain that was not adequately controlled by other pain-relievers, including opiates, found that Cannabis provided significant pain relief[320]. Research also demonstrates that the use of Cannabis and opiates is not associated with an increase in mortality[322].

More recent randomized clinical trials conducted by the CMCR have also demonstrated that smoked Cannabis is effective in treating neuropathic pain[323]. Researchers found that over half of patients with...
painful HIV peripheral neuropathy experienced pain reduction of more than 30% when treated with cannabinoids, a level of relief that pain researchers correlate to improved life quality. Such improvements occurred in two CMCR trials of patients with HIV peripheral neuropathies, and in a separate trial of patients with mixed neuropathic pain due to peripheral or central dysfunction of the nervous system[324-327].

Additional double-blind, placebo-controlled clinical trials indicate that Cannabis-based medicines may improve neuropathic pain associated with multiple sclerosis and mixed neuropathies resulting from herpes, trauma and vascular problems[126]. This research is also of particular importance to people with cancer, as many of its sufferers also experience neuropathic pain.

Finally, researchers have found that cannabinoids such as THC work in concert with opiate-based painkillers, to increase their combined effectiveness, particularly in cases of neuropathic pain. This evidenced synergy of Cannabis and opiates allowed patients to reduce their opiate dosage, minimizing the inherent risks of opiate use[328-331]. This entourage effect extends to other cannabinoids, with multiple studies finding that isolated synthetic cannabinoids such as THC (dronabinol) did not provide the same degree of efficacy as whole-plant preparations of Cannabis[104]. The ECS is proposed to interact with the endorphin system, both through the release of opioid peptides by cannabinoids and by the release of endocannabinoids by opioids[126,332]. Clinically, THC may enhance the pain relieving effects of opiates, effectively lowering the dose of an opiate necessary for relief[321,332]. Similarly, animal work on combined Cannabis and opiate administrations suggests that THC can decrease the side effects of opiates and may have a prophylactic effect on the dependence developed to opiate administration[333]. Data gathered from the U.S. in those territories that have legalized Cannabis for adult use, has evidenced significantly lower opiate-related mortality[322]. Surveys also suggest that Cannabis is often used to decrease the use of other drugs, most significantly opiate-based painkillers[334].

**Hepatitis-C Virus**

Cannabis may improve the effectiveness of drug therapy for the hepatitis C virus (HCV), a potentially deadly viral infection that affects more than 3 million Americans [335] and 130–150 million people globally. Treatment for HCV typically involves months of therapy with two powerful drugs – interferon and ribavirin – both of which have severe side effects, including extreme fatigue, nausea, muscle aches, loss of appetite, and depression. Due to the debilitating side effects of anti-HCV drug therapies, people often do not finish treatment, which worsens their symptoms and can promote irreversible harm to the liver.

Researchers from the University of California, San Francisco Medical School and the Organization to Achieve Solutions in Substance-Abuse (OASIS) found that “modest Cannabis use may offer symptomatic and virological benefit to some patients undergoing HCV treatment by helping them maintain adherence to the challenging medication regimen[336].” Other research has found that patients with HCV who used cannabinoids while undergoing combination ribavirin and interferon treatment were nearly three times more likely to complete their conventional medical treatment as compared to those participants who did not use cannabinoids.
These studies offer suggestive evidence that for patients fighting HCV, Cannabis-based medicine might significantly improve appetite, while offering concomitant psychological benefits such as a reduced prevalence of depression.

**Chronic Pain**

According to the American Academy of Pain Management, nearly 50 million Americans and more than 1.5 billion people worldwide suffer from chronic pain. Unfortunately, it is estimated that four out of every 10 people living with moderate-to-severe pain have yet to experience significant relief. After reviewing a series of trials in 1997, the U.S. Society for Neuroscience concluded that “substances similar to or derived from marijuana could benefit the more than 97 million Americans who experience some form of pain each year[267].”

Although a wide variety of prescription analgesic drugs are available for use in treating pain – from aspirin to oxycodone – none of these drugs can be seen as completely adequate, in light of the many, severe, and potentially deadly side-effects associated with continued opiate use.

By contrast, the safety record of Cannabis is remarkable, and centuries of use as an analgesic are well documented[337,338]. In their meta-analysis of the available data, the IOM acknowledged a wide historical use of Cannabis for pain, noting that “after nausea and vomiting, chronic pain was the condition cited most often to the IOM study team as a medicinal use for marijuana[160].” Currently, pain relief is by far the most common condition for which physicians recommend the use of cannabinoids.

Many well-designed, double-blind placebo-controlled clinical trials have demonstrated cannabinoids can reduce suffering due to neuropathic pain[175,324,339-342]. A broad review of the body of scientific research concerning the analgesic effects of Cannabis concluded that there is now unequivocal evidence that cannabinoids can be significantly anti-nociceptive (capable of blocking pain transmission) in known animal models of acute pain[332,343-346].” Further research shows that cannabinoids also produce an entourage effect that enhances the effectiveness of opiate painkillers. One animal study found that the pain-relieving dose of morphine was lowered with the addition of a simultaneous, small dose of THC. Codeine’s efficiency was similarly enhanced[332].

Both human and animal studies have demonstrated that cannabinoids can work synergistically with opioidergic drugs in relieving pain. Research suggests that both direct and indirect interactions between opioid and cannabinoid receptors can not only enhance analgesia but also reduce the development of tolerance to opiates in mammals. These interactions hold promise for developing therapeutic strategies that could provide better pain relief, with lower overall doses of opiates (oxycodone and hydrocodone), resulting in fewer dangerous, debilitating side effects that patients reliant on opiate pain-killers alone experience[346,347].

Some of the most encouraging clinical pain data involve the treatment of intractable cancer pain and hard-to-treat neuropathic pain, a type of chronic nerve pain that resists conventional treatment. Approximately 3-4.5% of the global population and somewhere between 25% and 45% of cancer patients experience neuropathic pain. Decades of research on Cannabis’ effectiveness in pain management include
several clinical human trials, with volumes of additional anecdotal evidence[318,348-353]. The prevailing scientific evidence suggests a significant efficacy of cannabinoids in treating neuropathic pain[126,175,318,339,354].

Multiple clinical trials have shown that a controlled-dosage whole-plant extract of Cannabis (nabiximols, GW Pharmaceuticals Ltd.) significantly relieves intractable cancer pain, and does so better than THC alone. A recent double blind, randomized, placebo-controlled trial of 360 cancer patients in 14 countries found that pain scores improved significantly with administration of Cannabis extract. Researchers report that the combination of natural cannabinoids in nabiximols "is an efficacious adjunctive treatment for cancer-related pain" for patients who do not get adequate relief from opiate painkillers such as oxycodone or hydrocodone[355,356].

Pain resulting from spinal cord injuries (SCI) may also be treatable with cannabinoid medicines. A research team in 2009 noted that “very few pharmacological studies have dealt specifically with neuropathic pain related to SCI,” suggesting that “[for] refractory central pain, cannabinoids may be proposed on the basis of positive results in other central pain conditions (e.g. multiple sclerosis).” Animal model research of SCI pain has shown that cannabinoids yield more consistent positive results than conventional analgesics such as opiates, which “decrease in efficacy with repeated treatment over time”. These investigations concluded that drugs targeting the body's cannabinoid receptors “hold promise for long-term use in alleviating chronic SCI pain[116].”

Researchers have also determined that neuropathic pain may be treatable via augmenting the body's natural supply of cannabinoids – the endocannabinoids. A study that inhibited two enzymes that normally break down the body's natural production of endocannabinoids found that preserving this efflux “reduces neuropathic pain through distinct receptor mechanisms of action” and that “[these compounds] present viable targets” for developing new analgesic drugs[357]. Drugs which can selectively target CB2 cannabinoid receptors – which are almost completely absent from the central nervous system – have also demonstrated suggestive therapeutic potential for both inflammatory and neuropathic pain control[358].

**Multiple Sclerosis**

One survey of people living with multiple sclerosis (MS) showed that more than 40% of respondents report using Cannabis to relieve symptoms of the disease. Among them, nearly three quarters stated that cannabinoid medicines mitigated their muscle spasms, and more than half reported a significant alleviation of their pain. A similar survey found that 96% of Canadians living with MS believe Cannabis is therapeutically useful for treating the disease. Of those who admitted using cannabinoids to treat their symptoms of MS, the majority cited significant relief of chronic pain, spasticity, and depression[359]. In addition, numerous studies have reported improvements in tremor, sexual dysfunction, bowel and bladder dysfunction, vision dimness, dysfunctions of walking and balance (ataxia), memory loss, pain, and spasticity[360-367].

In fact, cannabinoids have been shown to significantly lessen MS symptoms, and slow or halt the progression of the neurodegenerative disease in mammals. Cannabinoid-based medicines have demonstrated effects on immune function that might serve to reduce the autoimmune
neuroinflammatory response which drives relapsing neurological attacks resulting in increasing disability[368-370]. Clues as to why may lie in research that indicates that individuals with MS show increased levels of endocannabinoids in their blood, indicating perhaps that the endocannabinoid system “may be dynamically modulated depending on the subtype of the disease[371].”

Pre-clinical studies of the pharmacology of Cannabis have identified calming effects on those motor systems of the CNS that have the potential to positively affect tremor and spasticity. A controlled study of the efficacy of THC in an animal model of MS – experimental allergic encephalomyelitis (EAE) – demonstrated significant amelioration of these two most common MS symptoms. A review of six randomized controlled trials of Cannabis extracts (that combines THC and CBD) found “a trend of reduced spasticity in treated patients” and “evidence that combined THC and CBD extracts may provide therapeutic benefit for MS spasticity symptoms[369].” One such dosage-controlled THC-CBD whole-plant extract – the sublingual spray, nabiximols – has been shown in numerous clinical trials to ease pain, decrease spasm frequency, and improve bladder control and quality of sleep. Clinical trials of nabiximols found “a statistically significant and clinically relevant improvement in spasticity...and was well tolerated in MS patients[372].” As of June 2012, nabiximols is available by prescription in the UK, Spain, Germany, and Denmark for the symptomatic relief of spasticity, neuropathic pain, or both, in adults with MS. It has now been approved for distribution in Italy, Sweden, Austria, and the Czech Republic, with recommendations for approval in Belgium, Finland, Iceland, Ireland, Luxembourg, the Netherlands, Norway, Poland, Portugal, and Slovakia.

MS patients frequently report that cannabinoids can help alleviate bladder control issues, and a review of studies on cannabinoid receptors in the bladder notes that non-psychoactive cannabinoids are effective, and that the psychotropic effects of THC can be mitigated by delivering cannabinoids directly into the bladder[373]. While objective measures of spasticity in humans have not consistently shown benefits from cannabinoid treatment, a randomized clinical trial with 189 MS patients being treated with a Cannabis extract showed that 40% achieved greater than 30% improvement[374].

In addition to studying the potential role of Cannabis and its derivatives in the treatment of MS-related symptoms, scientists are exploring the potential of cannabinoids to inhibit neurodegeneration. A 2003 study that the National MS Society called “interesting and potentially exciting” demonstrated that cannabinoids were able to slow the disease process in mice by offering neuroprotection against EAE[375]. Only recently have scientists identified EAE as an animal model for MS, opening the door for future investigations research into MS symptom suppression.

**Other Movement Disorders**

Muscular spasticity is a common condition, affecting over 12 million people worldwide. It afflicts individuals who have suffered strokes, as well as those with MS, cerebral palsy, paraplegia, quadriplegia, and a variety of spinal cord injuries. Conventional medical therapy offers little relief for spasticity. Phenobarbital (a barbiturate) and diazepam (Valium, a benzodiazepine) are commonly prescribed, but they rarely provide complete relief and many patients develop a tolerance, become addicted, or complain of heavy sedation. These drugs also often cause muscle weakness, drowsiness, and a syndrome of various untoward other side effects that patients often find intolerable.
The therapeutic use of *Cannabis* for treating muscular spasticity and movement disorders has been known to Western medicine for nearly two centuries. In 1839, Dr. William B. O’Shaughnessy noted both the plant’s muscle relaxant and anti-convulsant properties, writing that medical doctors had “gained an anti-convulsive remedy of the greatest value.” Contemporary animal and human clinical studies reveal that *Cannabis* and its constituent cannabinoids may effectively treat movement disorders affecting older patients, including tremors and spasticity, because cannabinoids have a dose-dependent anti-spasticity, analgesic, anti-tremor, and anti-ataxic effect.

The contemporary understanding of the actions of *Cannabis* was advanced by the discovery of the endogenous cannabinoid system in the human body – the ECS – which appears to be intricately involved in regulating normal physiology. Central cannabinoid receptors are densely located in the basal ganglia, the area of the brain that controls body movement. Endogenous cannabinoids also appear to play a role in the manipulation of other transmitter systems within the basal ganglia – increasing transmission of certain chemicals, inhibiting the release of others, and affecting how still others are absorbed. Most movement disorders are caused by a dysfunction of the biochemical loops in this part of the brain. Research suggests that an endogenous cannabinoid “tone” participates in the overall control of movement. Endocannabinoids have modulating effects on the nervous system – sometimes to block neuronal excitability, while other times augmenting it. As scientists are developing a better understanding of the physiological role of endocannabinoids, it is becoming clear that these chemicals may be involved in the pathology of several neurological diseases. This means researchers are identifying an array of potential therapeutic targets within the human nervous system. They have determined that various cannabinoids found in the *Cannabis* plant modulate the synthesis, uptake, or metabolism of the endocannabinoids that underlie the progression of diseases such as Huntington’s, Parkinson’s, and tremors.

The neuroprotective qualities of *Cannabis* suggest an enormous potential for protecting the brain and central nervous system from the damaging effects of various diseases or injuries. Researchers have found that cannabinoids fight the debilitating effects of strokes, brain trauma, and spinal cord injury, as well as MS and neurodegenerative diseases. A neurodegenerative or neurological condition affects more than 52% of people over the age of 85. More than 100 research articles have been published on how cannabinoids act as neuroprotective agents, slowing the progression of a host of neurological disorders in mammals including amyotrophic lateral sclerosis, Huntington’s, Alzheimer’s, and Parkinson’s disease.

Modern research has demonstrated some promising therapeutic effects of cannabinoids to treat Parkinson’s disease and related motor neuron diseases. In one example, a female patient with Parkinsonian tremor who had failed conventional treatment claimed several hours of relief after smoking *Cannabis* on three different occasions. However, when she and four other treatment-resistant patients with tremor were administered *Cannabis*, no benefit was observed on tremor in any of them in comparison to diazepam, levodopa/carbidopa or apomorphine. Two subsequent clinical trials with *Cannabis*-based medicines to treat tremor of MS, with an obviously distinct pathophysiology, produced variable benefits in some patients employing an oromucosal spray or oral extract of THC and CBD, respectively. Data suggest that the symptom complex of Parkinsonism – including tremor,
bradykinesia, and dyskinesia – may respond to such treatment over a long time course.

The best evidence for cannabinoid efficacy in Parkinson’s derives from a survey performed in the Czech Republic – after a well-publicized television news magazine program presented the story of one Parkinson disease patient who improved all his symptoms with prolonged administration of an oral Cannabis preparation[391]. Parkinsonian patients at the Prague Movement Disorders Centre were sent an anonymous questionnaire to assess the effects of Cannabis on their various symptoms. Of 630 possible respondents, 339 questionnaires (53.8%) were returned. Eighty-five respondents (25.1%) reported using fresh or dried leaves taken orally approximately ½ teaspoon (2.5 ml) with meals once a day, usually in conjunction with their customary conventional medication. Almost none had prior experience of recreational Cannabis usage. In marked contrast to most surveys, only one respondent smoked the Cannabis. As a result of this oral Cannabis intake, 45.9% reported mild-to-substantial reduction in overall symptoms, with 30.6% noting reduced resting tremor, 44.7% alleviation of bradykinesia, 37.7% reduced muscular rigidity, and 14.1% reduction in dyskinesia associated with L-dopa medication. Noteworthy to the report was that only 4.7% felt that Cannabis intake exacerbated their condition.

A limited number of studies of CBD in Parkinson’s disease have also been completed in Brazil[396-398]. In the first study, six Parkinson’s patients with psychosis (each non-responsive for 3 months to conventional medications) were assessed in a four-week open label study. Patients were started on 150 mg CBD capsules in corn oil, with weekly increases according to clinical response[397]. Significant improvements were noted after CBD treatment in nearly all scored criteria, including anxiety and depression. No change was noted in motor function, nor were any cognitive changes observed.

A second study from Brazil selected 21 patients without psychiatric or dementia diagnoses from a larger cohort of 119 consecutive Parkinson’s diseases evaluations [396] and employed 300 mg CBD per day in corn oil capsules vs. placebo, in a double-blinded trial for six weeks. Capsules were administered only at night. After treatment, the CBD group showed positive results in the Parkinson’s Disease Questionnaire (PDQ-39) and the Activities of Daily Living and Stigma subscores.

A third Brazilian study examined a subset of Parkinson’s patients with rapid eye movement (REM) sleep behavior disorder[398]. Case studies and assessments were performed on four affected patients. Three of the patients went six weeks without episodes after taking 75 mg of CBD in corn oil capsules nightly, while the fourth required dose escalation to 300 mg a night to reduce episodes to once a week. All the patients experienced relapse to attacks of the prior frequency upon discontinuation of the CBD.

An Israeli study examined 22 patients who had received government permission to try smoked Cannabis for treatment-resistant Parkinsonian symptoms[399]. Participants used Cannabis continuously for more than two months. Six proved intolerant to Cannabis due to inability to inhale smoke, and side effects such as vomiting, dizziness, or psychosis. Motor scores improved after Cannabis in patients with or without daily response fluctuations. Specifically, improvements were noted in tremor, rigidity, bradykinesia, but only slightly on posture. Pain also diminished significantly, and 20 patients reported improvement in sleep.

The available evidence to date suggests a possible application of Cannabis-based medicines for
symptomatic treatment of Parkinson’s disease. Both THC and CBD components may contribute, but exact
dosing and/or appropriate ratios of these disparate cannabionoids are still unclear using available
data[400,401]. Documentation supports a benefit to inhaled and oral preparations, with the latter
seemingly preferable to patients given the requirement for chronic or life-long administration. No clear
drug-drug interactions have yet been noted. Overall, the data would suggest that prolonged trials of
Cannabis-based medicines may be necessary to assess overall benefit or lack thereof.

Arthritis

According to the Arthritis Foundation, arthritis is one of the most prevalent chronic health
problems and the nation’s leading cause of disability amongst Americans. A 2006 report estimated that
46 million Americans – nearly 1 in 5 adults – and 350 million people worldwide, live with chronic joint
pain and arthritis. Indeed, the use of cannabinoids as a treatment for musculoskeletal pain in western
medicine dates back to the 1700s[402]. Modern research confirms that Cannabis and related therapies
can relieve the pain associated with arthritis and the other rheumatic and degenerative hip, joint, and
connective tissue disorders. In their 1999 meta-analysis of the data then available, the IOM specifically
noted that the anti-inflammatory properties of cannabinoids could have therapeutic application in
preventing or reducing pain caused by swelling and inflammation (such as arthritis)[160].

Research has proven Cannabis and its constituent cannabinoids possess powerful immuno-modulatory
and anti-inflammatory properties that may be useful in treating chronic inflammatory diseases
directly[204,403-405]. Many patients and doctors report Cannabis has proven to be an effective
treatment for rheumatoid arthritis, and it is one of the recognized conditions for which many U.S. states
now permit medical use.

CBD has been shown to have numerous medical applications as an anti-inflammatory and
neuroprotective agent, including as a treatment for rheumatoid arthritis[406,407]. Research indicates
that CBD suppresses the immune response in mice and rats that is responsible for a disease state
resembling arthritis, protecting them from severe damage to their joints, and markedly improving their
condition [408-410]. In a randomized, double-blind, placebo-controlled trial in 58 human patients with
rheumatoid arthritis, nabiximols significantly improved pain, sleep quality, and a measure of disease
activity[124].

Specifically, Cannabis has a demonstrated ability to improve mobility and reduce morning stiffness and
inflammation, and research suggests that individuals can reduce their use of potentially harmful non-
steroidal anti-inflammatory drugs (NSAIDs) when using Cannabis as an adjunct therapy[405,411].

Alzheimer's Disease

Alzheimer’s disease is a neurodegenerative condition for which Cannabis and cannabinoid
therapies also show some promise, both for managing the symptoms and treating the underlying disease.
Agitation is the most common behavioral management problem in people with Alzheimer’s, affecting an
estimated 75% of people with the disease. It can include symptoms ranging from physical or verbal
abusive behavior to pacing and restlessness, as well as disruptive behaviors such as screaming and
repetitive requests for attention. Clinical research involving THC indicates that cannabinoids might significantly reduce the agitation common to Alzheimer’s sufferers[412-414]. THC has also proven effective in combating anorexia or wasting syndrome, another common problem for people with Alzheimer’s disease[415]. Alzheimer’s disease is widely believed to be associated with oxidative stress, due at least in part, to the membrane action of β- amyloid peptide aggregates. Recent studies have indicated that the Cannabis plant’s primary components – CBD and THC – provide a combination of neuroprotective, anti-oxidative and anti-apoptotic effects by inhibiting the release of the toxic β- amyloid peptide[416].

**Epilepsy and Seizure Disorders**

Peer-reviewed journal articles on the effects of Cannabis and related compounds from the plant have been largely limited to a concentrated series of preclinical animal studies, undertaken because Cannabis controls limit or prevent meaningful human clinical studies from being conducted in the U.S. There are thousands of published articles demonstrating the anti-convulsive and anti-epileptic effects of cannabinoid compounds in animals but that research is simply beyond the scope of this document, which focuses on human studies. In the absence of approved clinical research studies on Cannabis and epilepsy, the many anecdotal case reports of successful seizure control by individual patients must be assessed. Several documentaries have been filmed of parents using Cannabis extracts to treat childhood epilepsy. What follows are a number of compelling, though anecdotal, case reports of the benefit of a Cannabis-based therapy for seizures and convulsions[417].

**Cannabis, THC, and Seizures**

In the late 1940s, the effects of Δ9-THC were investigated in a small trial of five institutionalized, epileptic children whose seizures had previously been unresponsive to phenobarbital or phenytoin. The study found that "severe anticonvulsant resistant grand mal epilepsy [was] controlled" in two children with no change noted in the remaining three[418].

Shortly before the 1976 drug convention lead to the U.S. adopting regulations that severely limited Cannabis research, another case report was published, documenting a 24-year-old male on two concurrent antiepileptic drugs, who was not able to control his seizures. Rather, the patient used 2-6 Cannabis cigarettes per day to control his symptoms[419]. Since the 1976 drug convention, there have been few relevant case studies available, and those that are available tend to document the efficacy and safety of THC-based therapy as an anticonvulsant treatment in terminal pediatric patients[378]. Another study documented four relevant cases of children, ages 12 to 14, that were administered THC, causing a "noticeable reduction in the number of seizures" in these participants. More recently, Cannabis has been reported to produce a "marked improvement" in seizure control in a 45-year-old cerebral palsy patient, epileptic since age 18, who experienced premature birth as well as a concussion at age 8[420]. While these few anecdotal stories are quite compelling, they simply do not amply delineate Cannabis-based medicine for seizures.
CBD and Seizures

To date, CBD is the only phytocannabinoid other than THC with reported results for anticonvulsant effects in human subjects. The following is a review of studies on CBD used to treat seizure disorders in humans. In 1978, Mechoulam and Carlini randomized nine patients to either 200 mg/day of pure CBD or placebo[421]. During the three-month trial, two of four patients treated with CBD became seizure-free, whereas seizure frequency was unchanged in the five patients who received placebo.

A small (n=15) population of adult patients who exhibited partial seizures with secondary generalization that were uncontrolled by conventional treatment were enrolled in a double-blind, placebo-controlled, add-on study to examine the effect of CBD (≤300 mg/day) for 4.5 months[417,422,423]. Of the patients who received CBD (n = 8), four exhibited no sign of seizure, one “improved markedly,” one “improved somewhat,” one showed no improvement, and one withdrew from the study. The investigators concluded that CBD could be of benefit to patients with secondary generalized epilepsy for whom existing medicines were ineffective.

In a later, open-label clinical trial employing CBD (900–1200 mg/day for 10 months), "seizure frequency was markedly reduced in the patient” consistent with previous findings[424]. In yet another study, 12 epileptic patients were given CBD (200–300 mg/day) as an adjunct to existing treatments, but no change in seizure incidence was found[425]. The results of these studies were published in only abstract form, preventing full examination of the study details and insight into the relevance of the findings.

In 2005, a study reviewed population data of epileptic children resistant to conventional anti-epileptic medications. Subsequently, the researchers instituted treatment for some of these subjects using an oil-based formulation of CBD. In most of the treated children, an improvement of the crises was obtained in equal to, or higher than, 25%, wherein a clear improvement of consciousness and spasticity was observed. Specific incidence of side effects was not reported in this study; however, subjects suffered no side effects warranting discontinuation of the CBD solution.

In regards to existing research on epilepsy and Cannabis, most of the available human evidence suggests that both a reduction in incidence and severity of seizures, as well as physical and behavioral improvements in children and adults treated with either Cannabis or its preparations can be achieved.

Despite the potentially beneficial effects of Cannabis and its constituents in the management of epilepsy, the psychotropic effects of pure THC alone limits its widespread therapeutic use, particularly as an anticonvulsant where regular, repeated doses throughout a patient’s lifetime are necessary[98,426]. However, it is notable that not only are all currently approved anticonvulsant drugs associated with some significant motoric and/or cognitive side effects, but many epilepsy patients are unable to drive motor vehicles or maintain employment because of either the side effects of conventional drugs, the symptoms of the disease, or a combination of the two[417,427].
Glaucoma

Glaucoma is an eye affliction characterized by an increase in intraocular pressure. It can lead to blindness if it is not treated effectively. Several anecdotal reports observe that Cannabis has the power to reduce the fluid pressure within the eye (Hepler et al., 1976; Green, 1984; Grinspoon and Bakalar, 1997). The U.S. federal government sends approximately 1 pound of Cannabis cigarettes to each surviving glaucoma patient from a 1970’s Investigational New Drug (IND) program (there are currently two surviving patients with glaucoma)[57]. Despite documented treatment success for patients in the IND program, it was cancelled for political reasons. The surviving patients were grandfathered into the program and continue to receive Cannabis produced by the University of Mississippi.

Despite decades of documented anecdotal reports of Cannabis to treat glaucoma from this IND program, only two controlled studies evaluating the effects of THC on glaucoma patients have been approved[428,429]. In a randomized, double-blind, crossover, placebo-controlled clinical trial, Merritt et al. (1980) administered one Cannabis cigarette containing 2% THC to 18 adults suffering from glaucoma. Cannabis induced a significant reduction in intraocular pressure, but exhibited the following main adverse effects: various sensory alterations (100% of the cases), tachycardia and palpitations (44% of the cases) and postural hypotension (28%).

In the other randomized, double-blind, parallel group study against placebo, conducted 1 year later, Merritt et al. (1981) instilled eye drops containing 0.01, 0.05 or 0.1% THC in eight individuals suffering from glaucoma and hypertension (one eye received THC and the other one placebo). They then observed a significant reduction in intraocular pressure with 0.05 and 0.1% topical solutions of THC. The 0.1% topical solution of THC induced a mild hypotension, but most importantly, no psychotropic effects were observed with the three locally administered THC concentrations.

Psychiatric Disorders (Anxiety, Depression, and Related Mood Disorders)

Human studies on the effects of Cannabis on anxiety and depression or mood disorders include studies on THC, CBD, and whole plant material. Dosing consisted of a range between 5mg-30mg oral THC and a single clinical study looked at 0.5mg/kg THC for changes in mood and related behavior. For CBD, clinical studies examined oral doses ranging between 60mg-600mg and 1mg/kg for improvements in related mood disorders. Conversely blocking the active sites for THC with the CB1 receptor antagonist, rimonabant is capable of increasing stress and anxiety levels at an oral dose of 70mg.

Review of the Human Clinical Studies on Psychiatric Disorders

Anxiety and Mood Disorders

The effects of Cannabis on anxiety and depression may depend on the ratio of certain cannabinoids, the individual user, and the context in which it is used. One of the active ingredients of Cannabis can cause an acute and short-lasting episode of anxiety, which often resembles panic, in naïve users. For a naïve user, a dose of oral THC that is likely to start to induce anxiety is >5mg synthetic Δ9-THC (for a man of average weight) and a higher dose could induce both panic attacks and paranoias[94].
However, the same is not necessarily true for all cannabinoids.

In a study with 10 treatment-naive patients with generalized social anxiety disorder, 400mg oral CBD was shown to reduce anxiety compared to placebo. This anxiolytic effect was associated with significantly reduced regional cerebral blood flow (measured by uptake of 740MBq of 99mTc-ECD) in the left parahippocampal gyrus, hippocampus, and inferior temporal gyrus, while increasing cerebral blood flow (ECD uptake) in the right posterior cingulate gyrus[95]. Similarly, a study of 24 patients with social anxiety disorder found an association between CBD (600mg; n=12) and decreases in anxiety within the context of public speaking task[96].

In 1974, an interactive study between CBD and THC showed that CBD (60 mg), added to Δ9-THC (30 mg), changed the symptoms induced by THC alone in such a way that the subjects receiving the mixture showed less anxiety and more pleasurable effects[97]. In 1982, a study confirmed a similar effect with CBD (1 mg/kg), co-administered with THC (0.5 mg/kg), and this combination also significantly reduced anxiety indices in healthy volunteers[98].

An early study on Cannabis use in Jamaica revealed no significant differences between a group of 30 users, and matched controls with respect to mood, thought, or behavior[99]. An international study funded by the National Institute on Drug Abuse, examined a group of 47 long-term hashish users in Greece. Differences in the number of users within defined psychopathology, as compared to controls was accounted for by “personality disorders,” with more psychiatric abnormalities being observed in the moderate user group as compared to heavy users[100,101]. A few years later, another study documented that Cannabis users in Costa Rica believed that use helped with depression. No significant adverse effects, or development of adverse health effects resulting from Cannabis use were observed[44].

The effects of THC are not consistent and often may misrepresent the effects of whole Cannabis[102]. In a study of oral THC, healthy volunteers received two doses of THC (7.5 and 15mg by mouth) or placebo, across separate sessions, before performing tasks assessing facial emotion recognition and emotional responses to pictures of emotional scenes[102]. In this three-session, double-blind, placebo-controlled study, THC significantly impaired recognition of facial fear and anger, marginally impairing recognition of sadness and happiness. The subjective responses to THC were not consistently positive – of the 25 study participants, 15 indicated a desire to take the 7.5mg dose again, whereas only 11 out of 25 did so at the higher 15 mg dose. Just over half of the participants identified THC as “marijuana-like” (7.5mg: 56%; 15mg: 52%). This study parallels many other findings on this subject – the paradox between dampened amygdalar reactivity and increased physiological indicators of emotional response remains a mystery to be resolved. The authors concluded that this property could potentially increase the appeal of Cannabis to certain users. As Cannabis use can lead to reduced sensitivity to anxiety-provoking emotional signals in some people, this may facilitate certain social interactions, especially amongst individuals with social inhibition or related disorders.

It has been well demonstrated that ‘blocking’ or interfering with CB1 receptor signaling can increase anxiety. One study documented that the CB1 receptor antagonist/inverse agonist, rimonabant, increases anxiety induced by public speaking in healthy humans. The anxiogenic effects occurred selectively during anticipatory and performance speech, without interfering with the pre-stress phase, meaning that the
drug effects occurred selectively in response to an aversive situation[103].

Inhaled Cannabis and mucosal sprays – with precise amounts of key cannabinoid ingredients – do not induce the same side effects as pure THC controls[104]. Research suggests that a Cannabis “overdose” (i.e., anxiety, panic attack, etc.) can be treated (or prevented prophylactically) with foodstuffs such as pine nuts, lemons, basil and/or orange juice, as these foodstuffs share many relevant, pharmacologically active compounds[104].

Similar to the literature on the effects on Cannabis on anxiety, the effects of Cannabis on mood disorders are contradictory. For example, a group of authors published case reports suggesting Cannabis can cause an acute depressive reaction in those with underlying depression. However, their later case reports suggest Cannabis use can improve symptoms of bipolar disorders [31,101,105]. Cross sectional studies suggest that depression is associated with Cannabis use, and that Cannabis consumption is related to an increased risk of depression later in life[13,106]. Likewise for anxiety, it has been noted that “Frequent cannabis users consistently have a high prevalence of anxiety disorders and patients with anxiety disorders have relatively high rates of Cannabis use[94].” It is unknown whether Cannabis use leads to a greater incidence of depression and anxiety later in life.

In one survey, Cannabis use and depression were not associated once medical use was taken into account[107]. In some cases, an illness (and not the use of Cannabis) may be causative factor for depression. Though there is a modest increase of risk amongst problematic users of developing depression or an anxiety disorder later in life, a recent meta-analysis found that that small, but statistically significant association between Cannabis and anxiety hinged on the inclusion of a single study[108]. While Cannabis may provide some benefit to anxiety or depressive/mood disorders in some individuals, the true relationship between Cannabis use and anxiety and depressive disorders later in life remains unsubstantiated by current research. Similar to anxiety, differential effects of Cannabis on depression may be due to differences in cannabinoid composition. Indeed, CBD has been shown to produce anti-depressant like effects similar to imipramine[109,110].

**Suicide and Suicidal Ideation**

Recent epidemiological work found no relation between the number of medical Cannabis users and completed suicides[111]. In fact, U.S. states that legalized the use of medical Cannabis were shown to have lower rates of suicide among men between the ages of 20 and 39, when compared to states that did not legalize medical Cannabis use[112].

Research among non-medical Cannabis using populations has received considerably more attention. Unfortunately, while some studies have shown associations between Cannabis use and heightened suicide ideation and attempts, a number of studies have either failed to control for confounds or, when they have, reported no association between Cannabis use and suicide[113-118].
There has been a recent emergence of empirical studies on the effects of Cannabis for symptoms of PTSD, borne primarily out of the observation that individuals with PTSD report using Cannabis to cope with PTSD symptoms; specifically, hyperarousal, negative affect, and sleep disturbances[119-121]. Indeed, empirical work has consistently demonstrated that the endocannabinoid system plays a significant role in the etiology of PTSD, with greater availability of cannabinoid type 1 receptors documented among those with PTSD than in trauma-exposed or healthy controls[122,123].

Unfortunately, there have been no randomized controlled trials (RCTs) of Cannabis for the treatment of PTSD. However, the use of Cannabis and oral THC has been implicated as a potential mechanism for the mitigation of many PTSD symptoms by way of its effects on the endocannabinoid system[430,431]. Consistent with this research, there has been one small RCT of nabilone that showed promise for reducing nightmares associated with PTSD. This retrospective study identified a 75% reduction in PTSD symptoms following Cannabis use among combat veterans with PTSD. In an unpublished pilot study of 29 Israeli combat veterans, reductions in PTSD symptoms followed the administration of smoked Cannabis, with effects seen up to one year post-treatment[432,433].

**Research on Cannabis and Gastrointestinal Disorders**

Crohn’s disease (CD) is an inflammatory bowel disease (IBD) that has no cure; treatment targets include reducing inflammation and secondary symptoms[434]. Between 16 percent and 50 percent of patients use Cannabis to relieve symptoms of IBD and patients using Cannabis for 6 months or longer are five times more likely to have had surgery for their IBD[202,435-437]. Only one placebo-controlled study of the effects of Cannabis in patients with CD has been conducted[436]. This study found that there was no difference between placebo and smoked Cannabis on CD remission, defined as a CD Activity Index (CDAI) of less than 100, and that Cannabis was superior to placebo in promoting clinical response (a decrease in CDAI score greater than 100), reducing steroid use, and improving sleep and appetite[436].

Many researchers have concluded that pharmacological modulation of the endogenous cannabinoid system provides new treatment options for a number of gastrointestinal diseases, including nausea and vomiting, gastric ulcers, IBD, CD, secretory diarrhea, paralytic ileus and gastroesophageal reflux disease[438-440].

---

**List of Medical and Scientific Organizations that have Issued Letter of Support for Medical Cannabis**

Numerous professional, medical, and scientific organizations, have issued their support for medical cannabis programs through public statements and testimony. A few examples are listed below:

- *The National Cancer Institute, one of 11 federal agencies under the National Institutes of Health, changed its website to include Cannabis as a Complementary Alternative Medicine, with possible benefits for people living with cancer.*  [http://www.cancer.gov/about-cancer/treatment/cam/hp/cannabis-pdq - section/all](http://www.cancer.gov/about-cancer/treatment/cam/hp/cannabis-pdq - section/all)

- *“Based on much evidence, from patients and doctors alike, on the superior effectiveness and safety of whole cannabis (marijuana) compared to other medicines for many patients — suffering from the nausea associated with chemotherapy, the wasting syndrome of AIDS, and the symptoms of other illnesses ... we hereby petition*
the Executive Branch and the Congress to facilitate and expedite the research necessary to determine whether this substance should be licensed for medical use by seriously ill persons.” - American Academy of Family Physicians

The American Medical Association “urges that marijuana’s status as a federal Schedule I substance be reviewed with the goal of facilitating the conduct of clinical research and development of cannabinoid-based medicines.”

The American College of Physicians “urges an evidence-based review of marijuana’s status as a Schedule I controlled substance to determine whether it should be reclassified to a different schedule.”

The American Public Health Association “adopted a resolution […] which urged federal and state drugs laws to exclude Marijuana as a narcotic drug,” and “conclude[d] that cannabis was wrongfully placed in Schedule I of Controlled Substances, depriving patients of its therapeutic potential.”

“Marijuana should be available for appropriate medicinal purposes, when such use is in accordance with state law, and that physicians who recommend and prescribe marijuana for medicinal purposes in states where such use is legal, should not be censured, harassed, prosecuted or otherwise penalized by the federal government.”- American Preventive Medical Association

“The Texas Medical Association supports (1) the physician’s right to discuss with his/her patients any and all possible treatment options related to the patients’ health and clinical care, including the use of marijuana, without the threat to the physician or patient of regulatory, disciplinary, or criminal sanctions; and (2) further well-controlled studies of the use of marijuana with seriously ill patients who may benefit from such alternative treatment.”

The Rhode Island Medical Society has stated that “[T]here is sufficient evidence for us to support any physician-patient relationship that believes the use of marijuana will be beneficial to the patient.”

A 2004 testimony from the New York County Medical Society stated, “The definitive review of scientific studies … found medical benefits related to pain relief, control of nausea and vomiting, and appetite stimulation. … While there are a variety of ways of supplying marijuana for medical use, serious consideration should be given to the 1997 recommendation … that the FDA reclassify marijuana from Schedule I and provide a consistent, safe supply.”

“The American Medical Student Association strongly urges the United States Government … to meet the treatment needs of currently ill Americans by restoring the Compassionate (Investigational New Drug) program for medical marijuana, and … reschedule marijuana to Schedule II of the Controlled Substances Act, and … end the medical prohibition against marijuana.”

“The National Nurses Society on Addictions urges the federal government to remove marijuana from the Schedule I category immediately, and make it available for physicians to prescribe. NNSA urges the American Nurses’ Association and other health care professional organizations to support patient access to this medicine.”- The National Nurses Society on Addictions

“The American Cancer Society supports the need for more scientific research on cannabinoids for cancer patients, and recognizes the need for better and more effective therapies that can overcome the often debilitating side effects of cancer and its treatment. The Society also believes that the classification of marijuana as a Schedule I controlled substance by the US Drug Enforcement Administration imposes numerous conditions on researchers and deters scientific study of cannabinoids. Federal officials should examine options consistent with federal law for enabling more scientific study on marijuana.
The above list represents a small portion of organizations that have offered their support for access to medical Cannabis.

**FACTORS 4 & 5: ITS HISTORY AND CURRENT PATTERN OF ABUSE & THE SCOPE, DURATION, AND SIGNIFICANCE OF ABUSE**

To assess drug abuse patterns and trends, data from different sources have been analyzed such as National Household Survey on Drug Abuse (NHSDA), Monitoring the Future (MTF), Drug Abuse Warning Network (DAWN), and Treatment Episode Data Set (TEDS) have been analyzed.

According to a recent United Nations (UN) report, the prevalence of Cannabis use in the Netherlands, where Cannabis has been de facto legal for the last 40 years, is lower than in many other European countries, the U.S. and Canada[441]. Four jurisdictions in the U.S. have legalized Cannabis, those are Colorado, Alaska, Washington state and Washington, DC.

It is estimated that somewhere between 3.3-4% of the world’s population (age 16-64 years) used Cannabis once in the last year according to the UN Office on Drugs and Crime.

**Use and Abuse**

The reviews of marijuana rescheduling petitions by government agencies do not distinguish between use and abuse according to professional standards, such as those in use by the medical and scientific community. There are existing standards such as the ICD-10 codes, which distinguish between use, abuse, and dependence[442]. Widespread use of Cannabis is not an indication of its abuse potential, and widespread use of marijuana without dependency supports the argument that marijuana is safe for use under medical supervision.

Since marijuana, heroin and other drugs are often referred to as “drugs of abuse”, many consider each use of these drugs “abuse”. That a clear differentiation between the two terms if often lacking is suggested by
Wish (1990), who noted in an editorial of *the Journal of the American Medical Association* on drug screenings in the workplace that a discussion on the difference between drug use and drug abuse was often regarded as "anachronistic and unpatriotic."[443]."  

However, the term "substance abuse" is clearly defined and should be differed from simple and unproblematic use, which is the rule and not the exception with most drugs, even in adolescents. Scientists usually differentiate between use, and forms of problematic use. The most frequent terms for problematic or pathological use are abuse, misuse, harmful use and dependency (e.g. Gorman and Derzon 2002, Swift et al. 2001)[444,445]. Definitions for these terms vary so that samples determined using different definitions overlap. Swift et al. (2001) compared dependency according to the DSM-IV (Diagnostic Manual of Diseases) to the concept of dependency in the ICD-10 (The International Classification of Diseases, 10th Revision) in a sample of 10,641 representative Australian adults:

"The prevalence of DSM-IV (1.5%) and ICD-10 (1.7%) cannabis dependence was similar. DSM-IV and ICD-10 dependence criteria comprised uni-dimensional syndromes. The most common symptoms among dependent and non-dependent users were difficulties with controlling use and withdrawal, although there were marked differences in symptom prevalence. Dependent users reported a median of four symptoms. There was good to excellent diagnostic concordance (kappas = 0.7-0.9) between systems for dependence but not for abuse/harmful use (Y = 0.4). These findings provide some support for the validity of cannabis dependence."

According to the newer DSM-IV definition Cannabis abuse and dependency will be observed more often than according to the criteria of the earlier DSM-III-R:

"We assessed a clinical sample of 102 adolescents using CIDI-SAM. Prevalence of either an abuse or dependence diagnosis was lower with DSM-IV than DSM-III-R except for cannabis and alcohol, and concordance rates were better for dependence than for abuse. For most substances, rates of DSM-IV withdrawal were lower than in DSM-III-R, but rates of DSM-IV physiological dependence remained high. Changes in DSM-IV criteria appear to have impacted diagnoses in these adolescents, particularly for the substances they use most--i.e. alcohol, tobacco, and cannabis[446]."

Clinical criteria for substance abuse according to DSM-IV are:

A. A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one or more of the following occurring within a twelve-month period.

(1) Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g. repeated absences or poor work performance related to substance use, substance related absences, suspension, or expulsions from school; neglect of children or household).

(2) Recurrent substance use in situations in which it is physically hazardous (e.g. driving an automobile or operating a machine when impaired by substance use).
(3) Recurrent substance related legal problems (e.g. arrest for substance related disorder conduct).

(4) Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by effects of substance (e.g. arguments with spouse about consequences of intoxication, physical fights).

B. Symptoms have never met the criteria for substance dependence for this class of substance.

When talking about the gateway theory, the Institute of Medicine (Joy et al. 1999) pointed out that it is necessary to differentiate between use and dependency or abuse to draw the right conclusions from given data:

"Many of the data on which the gateway theory is based do not measure dependence; instead, they measure use -even once-only use. Thus, they show only that marijuana users are more likely to use other illicit drugs (even if only once) than are people who never use marijuana, not that they become dependent or even frequent users. The authors of these studies are careful to point out that their data should not be used as evidence of an inexorable causal progression; rather they note that identifying stage-based user groups makes it possible to identify the specific risk factors that predict movement from one stage of drug use to the next-the real issue in the gateway discussion[171]."

Modern epidemiological studies have shown that many people who use Cannabis do not differ from other people, that they do not abuse the drug but use it. A survey of 15,000 British children aged 14 and 15 found that young people with high self-esteem are more likely to take illicit drugs than those whose self-confidence is low (Observer of 11 February 2001). The results contradict the concept that drug use is most prevalent among anxious or insecure youth looking for an escape from poor conditions or a way to feel better about themselves. Heather Ashton, a professor of pharmacology at Newcastle University, said that the results of the survey did not surprise her: "Students all report they take drugs for pleasure and that it has nothing to do with anxiety or stress. Years ago young people who take drugs were seen as psychotic or low risk-takers. Now that is not the case."

A report published by the Institute of Medicine provides an equally clear assessment of contemporary scientific standards for defining drug use, abuse, and dependency. The report "Pathways of Addiction, Opportunities in Drug Abuse Research" was published in 1996. According to its introduction:

"The report employs the standard three-stage conceptualization of drug-taking behavior that applies to all psychoactive drugs, whether licit of illicit. Each stage--use, abuse, dependence--is marked by higher levels of use and increasing serious consequences. Thus, when the report refers to the "use" of drugs, the term is usually employed in a narrow sense to distinguish it from intensified patterns of use. Conversely, the term "abuse" is used to refer to any harmful use, irrespective of whether the behavior constitutes a "disorder" in the DSM-IV diagnostic nomenclature. . . . It bears emphasizing that adverse consequences can be associated with patterns of drug use that do not amount to abuse or dependence in a clinical sense, although the focus of this report and the committee's recommendations is on the more intensified patterns of use (i.e. abuse and dependence) since they cause the
The findings above clarify marijuana’s abuse potential relative to other drugs; the use of more dangerous drugs is not a significant risk for most individuals whose consumption of marijuana can be described as use rather than abuse or dependence. These findings affirm that medical users of marijuana are not at risk to use of other illicit drugs due to their regular use of Cannabis.

The College on the Problems on Drug Dependence recognizes that marijuana is not a harmless drug, but they note a basis for distinguishing marijuana from drugs such as cocaine and heroin. They also note that serious questions have been raised as to whether marijuana is sufficiently dangerous to justify criminal sanctions, and are critical of DEA’s irrational scheduling decisions with respect to marijuana:

“Despite these significant adverse effects, questions have been raised by various investigative commissions about whether the social costs associated with the prohibition of marijuana are warranted by its actual harm to individuals and society, and especially whether imprisonment for mere possession unaccompanied by other crimes -- the law in some states -- is appropriate. It can be argued that placing marijuana in the same category as heroin and cocaine also sends a counterproductive message because it erases distinctions among drugs with very different degrees of hazard.” (College on the Problems of Drug Dependence Annual Meeting, 1997).

Gorman (2002) uses data from several prospective longitudinal studies (N= 3206) to examine the association between three psychological constructs on the use, misuse, and abuse of marijuana – providing an example of research and analytical strategies that incorporate the distinctions discussed above[444]. Many drug users not only do not move on to more dangerous drugs, many of them also stop using drugs on their own as they age.

“[This research] examined patterns of illicit drug use, abuse, and remission over a 25-year period and recent treatment use. . . [utilizing] Retrospectively obtained year-to-year measures from the 1996-1997 survey included use and remission of sedatives, stimulants, marijuana, cocaine, and opiates, as well as substance abuse and psychiatric treatment use. . . Most drug abusers who had started using drugs by their early 20s appeared to gradually achieve remission. Spontaneous remission was the rule rather than the exception. Nonetheless, considerable unmet needs existed for those who had continued use into middle age[447,448].”

Abuse of Cannabis

Several studies demonstrate that abuse rates for Cannabis are lower than rates for other common drugs. Cannabis use is usually not problematic use and Cannabis users usually have no social problems,
which can be attributed to Cannabis. The abuse potential of Cannabis is insufficient to justify prohibition of medical use.

Several studies demonstrate that abuse rates for Cannabis are lower than rates for other common drugs. Cannabis use is usually not problematic use and Cannabis users usually have no social problems, which can be attributed to Cannabis. The abuse potential of Cannabis is insufficient to justify prohibition of medical use.

In a sample of 10,641 Australians aged 18 years and older, 2.2% of adults were diagnosed with DSM-IV Cannabis use disorder, comprising Cannabis dependence (1.5%) and Cannabis abuse (0.7%)[445]. In this sample, 21% of Cannabis users met criteria for Cannabis dependence and 10.7% for abuse. Thus, there were a considerable number of Cannabis users in this sample with substance use disorders without being dependent. In this sample, Cannabis dependence was twice as likely to occur as Cannabis abuse.

Most Cannabis use is not problematic even for adolescents. In a survey of 2641 UK school students aged 15-16 years, 201 students reported having used Cannabis 40 times or more. They were examined using cluster analysis and also compared to other students.

“Three clusters of heavy cannabis users emerged. The smallest was largely distinguished by antisocial behaviour. Another cluster were clearly unhappy, with little support from parents and friends, high levels of depressed mood and low levels of self-esteem. The largest cluster were 'ordinary' and had little to distinguish them apart from a belief that their environment was stable and predictable and that society's rules should be obeyed. Although clear relationships emerged between heavy cannabis use and heavy use of other substances, the 'ordinary' cluster of heavy cannabis users were less likely than the others to have used other illicit drugs. It is therefore concluded that teenage heavy cannabis users have varied motivations and contexts for their usage. They should not be seen as a homogeneous group and many do not appear to use other illicit drugs[449].”

Often Cannabis users are treated as a homogeneous group, usually when attempting to analyze a correlation with the use of other drugs, with mental illnesses (depression, schizophrenia), or to find predictors for a certain development (e.g. Griffin et al. 2002, Degenhardt et al. 2001). Degenhardt et al. (2001) analyzed relationships between alcohol, Cannabis and tobacco and indicators of mental health problems[450]. Alcohol users had lower rates of affective and anxiety disorders than non-users of alcohol, while those meeting criteria for alcohol dependence had the highest rates. Tobacco and Cannabis use were both associated with increased rates of all mental health problems examined.

However, after controlling for demographics, neuroticism and other drug use, Cannabis was not associated with anxiety or affective disorders. Alcohol dependence and tobacco use remained associated with both of these indicators of mental health. All three types of drug use were associated with higher rates of other substance use problems, with Cannabis having the strongest association. It should be noted that researchers differentiated alcohol use and alcohol dependence and found very different results, while no such differentiation was made for Cannabis.
It is well established that most users of legal drugs, notably alcohol, tobacco and caffeine, control their use and are not generally considered to be abusing the drug. It appears from cluster analyses that this is also the case with Cannabis and that studies, which do not use cluster analyses and do not distinguish use from problematic use will overlook relevant information.

The associations that are found with Cannabis have also been found with legal drugs. Degenhardt and Hall (2001) examined the comorbidity between tobacco use, substance-use disorders and mental health problems among Australian adults aged 18 years and over[451]. DSM- IV diagnoses of substance use, anxiety, and affective disorders were derived using the Composite International Diagnostic Interview (CIDI). Other measures included a screener for psychosis and measures of psychological distress and disability. Researchers found that current tobacco use was strongly associated with abuse/dependence upon alcohol, Cannabis, and other substances, and with higher rates of anxiety and affective disorders. Current smokers were more likely to screen positively for psychosis and reported greater psychological distress and disability than non-smokers and persons who had never smoked. These higher rates of other problems were not explained by differences in demographic characteristics, neuroticism scores, or by use of other drugs. The authors concluded:

"Current tobacco use is associated with a range of other substance-use and mental health problems. These are likely to reduce the success of attempts to quit smoking. The presence of these other problems needs to be considered when considering smoking-cessation treatment, and further research may provide information on more effective treatment strategies for persons with co-existing substance-use and mental health problems."

Another article by Degenhardt et al. found that psychosis in a sample of 6,722 Australian adults were associated with the regular use of tobacco, alcohol, Cannabis and opiates[450].

"Ninety-nine persons (1.4%) screened positively for psychosis. Regular tobacco, alcohol and cannabis use were much more common among persons screening positively, as were alcohol, cannabis and other drug use disorders. Among alcohol and cannabis users, psychosis 'cases' were much more likely to be dependent. Ordinal logistic regressions revealed that regular tobacco use, cannabis and alcohol dependence, and opiate abuse were predictors of psychosis scores[450]."

For marijuana, even simple associations between an undifferentiated group of users and commonly believed attributes, for example that Cannabis users are not ambitious in sports or at work, cannot generally be established. The French Monitoring Centre for Drugs and Drug Addictions (OFDT) conducted a national school survey on the relationship between sporting activities and alcohol, cigarette and Cannabis use among adolescents[452]. Respondents were asked confidentially by self-administered
questionnaire (pen and paper) about their use of licit and illicit drugs and life-style (including sporting activities outside school: hours per week, registration in a club, type of sport).

The U-shaped curve between the intensity of physical activities and licit and illicit drug use appeared not to be systematic. It depended mainly on the product and the level of use. It only remained significant for boys and heavy smoking once gender and age effect were taken into account. The results stress the need to control for age and gender when the survey participants are teenagers. The relationship between drug use and sporting activity also depends on the type of sport[452].

One criteria of substance abuse deals with the "failure to fulfill major role obligations at work, school, or home." There are several studies dealing with the effects of Cannabis use on school and work performance, with conflicting results.

McDaniel (1988) analyzed the relationship between pre-employment drug use and on-the-job performance and found only a small positive correlation[453]. Blank and Fenton (1989) found a positive association between positive pre-employment testing for marijuana and later dismissals[454]. On the other side, Parish (1989) did not find any relation between pre-employment drug testing result and performance at work[455]. Normand et al. (1990) did not find any association between drug test results and subsequent change in employment[456]. Zwerling et al. (1990) noted a positive association between Cannabis use and change of occupation, absenteeism and discipline related problems at work[457]. One year later they reassessed the same cohort and found that there was no longer an association between Cannabis use and absence from work, while discipline-related problems had decreased[458]. These studies relied on results from pre-employment drug testing and suggest that only a minor sub-set of Cannabis users suffers from problems at work.

A study by Braun et al. (2000) demonstrated that the Cannabis effect is modulated by cultural aspects[459]. This was a nearly population based study on the prospective interrelationship of smoking, alcohol intake, marijuana use, and educational and occupational attainment of black and white young adults. Researchers used data from the U.S. CARDIA study (Coronary Artery Risk Development in Young Adults), which involved 5,115 persons 18-30 years of age during the 1985-86 period, who were reevaluated in 1987/88, 1990/91, 1992/93 and 1995. At the start of the study, 28.0% stated that they had used Cannabis in the past month. In the following 10 years, Cannabis use was negatively associated with completion of college. However, this negative association was only found in the younger sub-set aged 18-24 years at the start of the study, while in the older sub-set there was only a negative association between tobacco use and college completion. Associations of substance use with occupational measures were dependent on skin color.

"In Whites, marijuana use was associated with less prestigious occupations and lower family income, while smoking was unrelated and moderate daily drinking was positively associated. In Blacks, marijuana use was generally unrelated to occupational measures, while smoking and daily alcohol consumption were negatively associated(Braun:2000jd)."
Another criteria of substance abuse deals with "recurrant substance use in situation in which it is physically hazardous (e.g. driving an automobile or operating a machine when impaired by substance use)." Culpability studies provide the best data on the problems Cannabis can cause in the context of driving. This method studies crashes post hoc based upon information (usually from coroners and/or police data) about the causative factors of a crash and blood analyzes on drugs. Examination of these causative factors permits the researchers to apportion a score for each crash-involved driver to determine culpability for the crash. Although there are some differences between studies, these scores classify each driver as "culpable", or "not culpable" for the crash. The cases are then divided into groups according to the results of the blood analysis. Those drivers who had no detectable drugs in blood constitute the control group.

A recent analyzes summarizes:

"To date (September 1999), seven studies using culpability analysis have been reported, involving a total of 7,934 drivers. Alcohol was detected as the only drug in 1,785 drivers and together with cannabis in 390 drivers. Cannabis was detected in 684 drivers and in 294 of these was the only drug detected. (...) Using the culpability analysis method the dominant role of alcohol in motor vehicle accidents is clearly demonstrated, confirming the results with the case-control method. The results to date of crash culpability studies have failed to demonstrate that drivers with cannabinoids in blood are significantly more likely than drug-free drivers to be culpable in road crashes[460]."

If urine instead of blood is analyzed, predominantly drivers with regular Cannabis use will be found and not those actually impaired since Cannabis use can be detected for some weeks in the urine of heavy users. In a U.S. study with 414 injured drivers, 32 of the urine samples were positive for at least one potentially impairing drug[461]. Marijuana was detected most frequently (17%), surpassing alcohol (14%). Compared with drug- and alcohol-free drivers, the odds of crash responsibility were higher in drivers testing positive for alcohol alone (odds radio [OR] = 3.2) and in drivers testing positive for alcohol in combination with other drugs (OR = 3.5). Marijuana alone was not associated with crash responsibility (OR = 1.1). In a multivariate analysis, controlling for age, gender, seat belt use, and other confounding variables, only alcohol predicted crash responsibility. Researchers concluded:

"Alcohol remains the dominant drug associated with injury-producing traffic crashes. Marijuana is often detected, but in the absence of alcohol, it is not associated with crash responsibility[461]."

The first controlled, population based study on accidents on Cannabis users compared to non-users was conducted by Braun et al. (1998) in the U.S. Researchers and compared 4,462 individuals with different Cannabis use status (never, former, current use) with regard to frequency of injuries within three years[462]. Participants were randomly selected from 64,862 patients of a health maintenance program aged 15 to 49 years. All injuries independently of cause and severity were included. A total of 2,524 accident victims were treated outpatient, 22 were treated inpatient and 3 were fatalities. There was no association between Cannabis use and injuries.

The abuse potential of a certain substance can also be determined from the variation in the intensity of use over the course of several years. A high variability in intensity indicates a weak potential for
dependency and abuse. Von Sydow et al. (2001) determined incidence and patterns of the course of Cannabis use and disorders as well as cohort effects in a community sample of adolescents and young adults (n=2,446) aged 14-24 years at the outset of the study[463]. Patterns of Cannabis use, abuse and dependence (DSM-IV) were assessed using the Composite International Diagnostic Interview (M-CIDI). They reported the following results:

(1) Cumulative lifetime incidence for Cannabis use (at second follow-up): 47%; 5.5% for Cannabis abuse, 2.2% for dependence. (2) Men used and abused Cannabis more often than women. (3) The majority of the older participants (18-24 years at baseline) had reduced their Cannabis use at follow-up, while younger participants (14-17 years at baseline) more often had increased their use and developed abuse or dependence. (4) The younger birth cohort (born 1977-1981) tended to start earlier with substance (ab)use compared to the older birth cohort (1970-1977). (5) Cannabis use was associated with increasing rates of concomitant use of other licit and illicit drugs. The authors concluded:

"Cannabis use is widespread in our sample, but the probability of developing cannabis abuse or dependence is relatively low (8%). The natural course of cannabis use is quite variable: about half of all cannabis users stopped their use spontaneously in their twenties, others report occasional or more frequent use of cannabis[464]."

Felder and Glass (2001) explain that the abuse potential of Cannabis is not sufficient to preclude its medical use[465]. Their assessment of the relative abuse potential of Cannabis suggests that it does not have the high potential for abuse required for Schedule I or II status.

Much of the political and public objection to the use of THC or Cannabis as a therapy centers around its abuse potential and the belief by some that it serves as a "gateway" drug leading users to "harder" drugs of abuse. Many therapeutic drugs have abuse potential, yet this does not invalidate their role in current therapies. While there is some preliminary evidence for cannabinoids activating the reward pathways in the brain, most investigators have failed to find addictive or reinforcing effects of cannabinoids in animal models[466]. Unlike cocaine or heroin, cannabinoid agonists produce conditioned place aversion even at low doses and anxiogenic effects[467-469].

Furthermore, some species or varieties of animals will not self-administer cannabinoids and a lack of cross-sensitization between cocaine or amphetamines and cannabinoids has also been demonstrated[465,470-475]

A considerable number of Cannabis users suffer from problems that meet the criteria for abuse. However, the large majority of Cannabis users do not experience any relevant problems related to their use. When compared to legal drugs, abuse problems with Cannabis are generally less severe. The abuse of Cannabis does not preclude its medical use. Relative to other scheduled drugs Cannabis does not have a high potential for abuse.
Cannabis and Dronabinol

There is growing evidence that there is no relevant difference in subjective effects between (Schedule III) dronabinol and Cannabis. Thus, it can be expected that the abuse liability is similar for both agents.

In 1999, the Drug Enforcement Administration (DEA) reclassified dronabinol (Marinol) from a "Schedule I" drug to the less restrictive "Schedule III" category according to the Controlled Substances Act. This essentially means that instead of being classified with drugs like morphine, dronabinol is now classified with more widely used drugs like codeine. According to the Associated Press of July 3, 1999, Barry McCaffrey, director of the White House Office of National Drug Control Policy, said the capsule form of dronabinol is the "safe and proper way" to make components of marijuana available to the public and "this action will make Marinol, which is scientifically proven to be safe and effective for medical use, more widely available"

There are not many direct comparisons of the subjective and medicinal effects of Cannabis and dronabinol (THC, Dronabinol). Recent experimental research has shown that the subjective effects of Cannabis and THC are very similar[476]. The authors write:

"There has been controversy about whether the subjective, behavioral or therapeutic effects of whole plant marijuana differ from the effects of its primary active ingredient, Delta(9)-tetrahydrocannabinol (THC). However, few studies have directly compared the effects of marijuana and THC using matched doses administered either by the smoked or the oral form.

Two studies were conducted to compare the subjective effects of pure THC to whole-plant marijuana containing an equivalent amount of THC in normal healthy volunteers. In one study the drugs were administered orally and in the other they were administered by smoking.

In each study, marijuana users (oral study: n=12, smoking study: n=13) participated in a double-blind, crossover design with five experimental conditions: a low and a high dose of THC-only, a low and a high dose of whole-plant marijuana, and placebo. In the oral study, the drugs were administered in brownies, in the smoking study the drugs were smoked. Dependent measures included the Addiction Research Center Inventory, the Profile of Mood States, visual analog items, vital signs, and plasma levels of THC and 11-nor-9-carboxy-THC.

In both the oral study and the smoking study, THC-only and whole plant marijuana produced similar subjective effects, with only minor differences.

These results support the idea that the psychoactive effects of marijuana in healthy volunteers are due primarily to THC[476]."

Since the abuse potential of a drug is mainly attributed to its subjective effects it can be assumed that the abuse potential of THC and Cannabis are quite similar.
Clinical research has also demonstrated similar properties of THC and Cannabis with regard to therapeutic effects. This is shown in the data from marijuana research programs on the anti-emetic effects of marijuana in 6 states (Musty & Rossi 2001, see above), where patients who smoked marijuana experienced 70-100% relief from nausea and vomiting, and those who used the THC capsule experienced 76-88% relief[261]. In the study by Abrams et al. (2002) that investigated the interaction of smoked Cannabis and dronabinol (THC) with HIV medication, very similar effects were observed with regard to weight gain. The participants had been divided into three groups, with one set smoking Cannabis (3.95% THC), another taking oral dronabinol capsules (3x2.5 mg daily), and a third taking oral placebo capsules. Researchers found that those using dronabinol (THC) or Cannabis experienced significant increases in caloric intake and gained an average of 3.5 kg (marijuana group) and 3.2 kg. (THC group) compared to 1.3 kg in the placebo group. There was no significant difference between Cannabis and THC with regard to side effects and benefits.

Leo Hollister stated in a recent review on the medical use of Cannabis:

"Marinol or dronabinol, is available for treating nausea and vomiting associated with cancer chemotherapy and as an adjunct to weight loss in patients with wasting syndrome associated with AIDS. Although such approval currently applies only to orally administered THC, for practical purposes smoked marijuana should also be expected to be equally effective. Promising leads, also often fragile, suggest possible uses for treating chronic pain syndromes, neurological disease with spasticity and other causes of weight loss. These indications require more study."

The American public notes that the difference between Cannabis and dronabinol with regard to classification is hypocritical and political. Journalist Cynthia Cotts commented the reclassification of Marinol from Schedule II to Schedule III in the Nation on September 20, 1999:

"For more than half a century, the U.S. government has maintained a hard line on marijuana, denying that the plant has any medical value at all. But in the period since 1996, during which voters in several states have approved the medical use of marijuana and the Institute of Medicine has hailed the therapeutic effects of THC (one of the cannabinoids found in the natural plant), the Feds have scrambled to revise their position. Now, the drug warriors’ line goes something like this: Who needs pot, an illegal substance that burns up your lungs, when you can take Marinol (dronabinol), a little white pill that contains synthetic THC? The government threw its weight behind Marinol this past July, when the Drug Enforcement Administration moved the drug into Schedule III, lifting its dangerous stigma and making it easier for doctors to prescribe. While drug czar Barry McCaffrey insisted the move was based on "pure science," a review of the players involved suggests that the rise of Marinol is more the result of politics and profiteering[477]."
Cannabis as Gateway Drug

Recent research suggests that recreationally used Cannabis does not act as a gateway drug to harder drugs such as alcohol, cocaine and heroine. The same will apply to users of medicinal Cannabis.

Several research studies addressed the question whether Cannabis leads to the use of harder drugs such as alcohol, cocaine and heroin. The Institute of Medicine study characterized marijuana’s role as a “gateway drug” as follows:

“Patterns in progression of drug use from adolescence to adulthood are strikingly regular. Because it is the most widely used illicit drug, marijuana is predictably the first illicit drug most people encounter. Not surprisingly, most users of other illicit drugs have used marijuana first. In fact, most drug users begin with alcohol and nicotine before marijuana—usually before they are of legal age.

In the sense that marijuana use typically precedes rather than follows initiation of other illicit drug use, it is indeed a “gateway” drug. But because underage smoking and alcohol use typically precede marijuana use, marijuana is not the most common, and is rarely the first, "gateway" to illicit drug use. There is no conclusive evidence that the drug effects of marijuana are causally linked to the subsequent abuse of other illicit drugs. An important caution is that data on drug use progression cannot be assumed to apply to the use of drugs for medical purposes. It does not follow from those data that if marijuana were available by prescription for medical use, the pattern of drug use would remain the same as seen in illicit use[171].”

A more recent study based on national survey data also does not support the hypothesis that increases in marijuana use lead to increased use of more dangerous drugs among the general public. In the American Journal of Public Health, Andrew Golub and Bruce Johnson of the National Development and Research Institute in New York wrote that young people who smoked marijuana in the generations before and after the baby boomers do not appear to be likely to move on to harder drugs[478]. The researchers said that these findings suggest that the gateway phenomenon reflects norms prevailing among youths at a specific place and time.

“The recent increase in youthful marijuana use has been offset by lower rates of progression to hard drug use among youths born in the 1970s. Dire predictions of future hard drug abuse by youths who came of age in the 1990s may be greatly overstated.”

Research also suggests that the “gateway theory” does not describe the behavior of serious drug users:

“The serious drug users were substantially different from high school samples in their progression of drug use. The serious drug users were less likely to follow the typical sequence identified in previous studies (alcohol, then marijuana, followed by other illicit drugs). They were more likely to have used marijuana before using alcohol, and more likely to have used other illicit drugs before using marijuana. We also found that atypical sequencing was associated with earlier initiation of the use of illicit drugs other than marijuana and greater lifetime drug involvement. These findings suggest that for a large number of serious drug users, marijuana does not play the role of a ‘gateway drug’. We conclude that prevention efforts which focus on alcohol and marijuana may be of limited effectiveness for youth who are at risk for serious drug abuse[479].”
Side Effects of the Legal Situation

The illegal status of Cannabis under most jurisdictions causes negative consequences for many with regard to their career, personal and professional relationships, suspension of driving privilege, and health.

In a book chapter on side effects of the medical use of Cannabis, Grotenhermen states:

“Natural cannabis products are illegal in most countries. For the most part, no legal distinction is made between recreational and medical use. If single cannabinoids (dronabinol, nabilone) that may be legally prescribed in some countries are not available, too expensive, or ineffective, therapeutic use of cannabis may provoke various repercussions for the patient who employs it. These include: criminal prosecution or fear thereof, paying a high price for an illegal drug, exposure to possible contamination, use of an unknown concentration of THC with possible variability in dosing, limited forms of administration, and even fear of discussion with the patient's family doctor. The illegality of cannabis presents various obstacles to clinical research[168]."

At this time, U.S. law on the federal level and in most states treats the medicinal and recreational uses of marijuana and related acquisition alike. Thus, the legal situation of medical Cannabis users is subject to the same negative implications of law enforcement and penalization.

FACTOR 6: WHAT, IF ANY, RISK THERE IS TO THE PUBLIC HEALTH

This section discusses research on public health priorities regarding prenatal and adolescent exposure, Cannabis use and the workplace, and emergency room visits. Additionally, a summary of the toxicological data from Factor 1 is discussed here.

Overview Prenatal and Adolescent Exposure to Cannabis

Cannabis and cannabinoids are recommended and prescribed to treat neurological disorders, and are not associated with causing significant neurological problems or having a toxic effect on development in controlled research studies[60,62,66,101,126,417,480]. A CDPHE Retail Marijuana Public Health Advisory Committee review of Cannabis and pregnancy states that negative effects associated with prenatal exposure to Cannabis are “mixed” and “limited” because research does not show significant harms to IQ, brain structure and function (Kathryn Wells, MD. Pediatric Marijuana Exposure DDHS Training August 11, 2015)[481]. Despite evidence that THC can be present in breast milk, there is no evidence to support the claim that THC has profound and long-lasting consequences for the brain. A recent study confirms the safety profile of Cannabis, “maternal marijuana use does not increase the risk of adverse obstetrical outcomes or fetal anomalies[482]."
Exposure to Cannabis and related products may produce acute side effects such as anxiety, paranoia, or temporally inhibiting memory. However, there is no supporting evidence that indicates that these side effects predict the development of conditions (such as anxiety condition or other mental health issue) later in adult life. There is also no significant impact on IQ or scholastic performance regardless of the amount of Cannabis use or exposure, once other factors are controlled for (tobacco, alcohol, access to medical care, brain injuries (stroke, concussion), etc).

**Children (Development Pre- and Post-Natal)**

The science demonstrates that cannabinoid receptor activation (i.e. CB₁ and CB₂ receptors) is a natural and important component for proper development[483]. Mammals, including humans, produce endocannabinoids, which are THC-like compounds. These THC-like compounds include Anandamide and 2-AG. Anandamide and 2-AG activate the same receptors as THC, and are found in bovine and human breast milk[484]. Adding THC to the mix of endocannabinoids in breast milk may lead to changes in development but scientists have no significant evidence that the differences in rats and mice translate into long-term negative changes in human development because[151]. For example, rats exposed to THC during adolescents are protected from developing opiate dependence, which suggest Cannabis use could prevent developing dependence or addiction to other drugs [333].

The claims of negative developmental effects from THC exposure remain unsubstantiated but the blocking of cannabinoid receptor activation during early development is considered to have “catastrophic” effects. Studies by Ester Fride and colleagues have demonstrated the importance of having an endocannabinoid system that is actively functioning[66,101,483,485-487]. For example, one of the studies by Fride et al. showed that the administration of SR141716A, a drug which prevents CB₁ receptor activation by THC and anandamide, will kill 50% of baby mice within 2 days, due to a disruption of feeding behavior[488]. In another experiment from the same study, THC was able to reverse the rate of death and disruption in feeding behavior induced by SR141716A.

Studies in mice and rats have shown that prenatal or postnatal exposure to Cannabis or cannabinoids may lead to subtle changes in breast milk and development. However, many of these animal studies do not have much, if any human data to corroborate them. Drugs abuse studies are often difficult to interpret, as most subjects use multiple drugs and socioeconomic status seems to play the biggest role—money, health care, and your parents level of education can have a bigger impact on healthy development than Cannabis[489].

Many studies have looked at the effect of Cannabis use during pregnancy and the results suggest that there are not clear consequences. A review article published by Dr. Ethan Russo walks the reader through the human studies on pregnancy, here are some of the examples from his article[490]:

“A variety of studies have demonstrated transient effects of cannabis on endocrine hormone levels, but no consistent effects seem to occur in chronic settings[490].”

“Studies are hampered by the obvious fact that laboratory animals are not human in their responses. Estrous cycles and behaviors in animals are not always analogous to menstrual cycles and other physiological effects in women[490].”
“In a study of 171 women, 25% of pregnancies ended spontaneously within 6 weeks of the last menses. Cannabis exposure seemed to have no observable effect in these cases[491].”

“In 1987, the Ottawa group compared effects of cannabis, tobacco, alcohol and caffeine during gestation. Whereas tobacco negatively affected neonatal birth weight and head circumference, and alcohol was associated with lower birth weight and length, no effects on any growth parameters were ascribable to maternal cannabis usage[492].”

“In a subsequent study, examination of 8350 birth records revealed that 417 mothers (5%) claimed cannabis-only usage in pregnancy, but no association was noted with prematurity or congenital anomalies. The authors suggested that previously ascribed links to cannabis were likely confounded by concomitant alcohol and tobacco abuse[493].”

“A group in Boston noted a decrease in birth weight of 79 g in infants born to 331 of 1226 surveyed mothers with positive using drug screen for cannabis (p =0.04), but no changes in gestation, head circumference or congenital abnormalities were noted[494].”

“The largest study of the issue to date evaluated 12,424 pregnancies. Although low birth weight, shortened gestation and malformations seemed to be associated with maternal cannabis usage, when logistic regression analysis was employed to control for other demographic and exposure factors, this association fell out of statistical significance[495].”

“Dreher has extensively examined prenatal cannabis usage in Jamaica wherein the population observations were not compounded by concomitant alcohol, tobacco, or polydrug abuse[496,497]. This study is unique in that regard, no less due to the heavy intake of cannabis (“ganja”), often daily, in this cohort of Rastafarian women. No differences were seen between groups of cannabis-using and non-cannabis-using mothers in the weight, length, gestational age or Apgar scores of their infants. “Deleterious effects on progeny of cannabis smokers were not apparent; in fact, developmental precocity was observed in some measures in infants born to women who smoked ganja daily[496].”

Researchers have administered THC and other cannabinoids to children; cannabinoids may have a role in pediatric medicine as young children do not appear to get “high” from cannabinoids such as THC[498]. Below is a discussion of two of the clinical trials on cannabinoids and children.

“The gradual postnatal increase of anandamide and its CB1 receptors is accompanied by a gradual maturing response to the psychoactive potential of D9-tetrahydrocannabinol and anandamide in postnatal mice between birth and weaning[499].”

This observation has important implications for cannabinoid therapy in children, since psychoactive side effects may be expected to be minor when treated with cannabinoids at a young age. Indeed, very high doses of D8-tetrahydrocannabinol (approximately 0.64 mg/kg/treatment) were given to children between the ages 3 and 13 years who were undergoing chemotherapy for the treatment of various hematologic cancers, over long periods of time (up to 114 treatments, based on 4 treatments/24h during the days of chemotherapy). The anti-emetic effects were impressive, whereas the side effects were
minimal[500].

In a report entitled, *On the application of cannabis in paediatrics and epileptology*, eight children (ages 3-14 years) with a variety of severe neurological diseases were treated with D9-tetrahydrocannabinol (0.04-0.12 mg/kg/day) [378]. Significant improvements in behavioral parameters including reduced spasticity, improved dystonia, increased interest in the surroundings and antiepileptic activity were reported without notable adverse effects[378].

It is not clear, how, in the first study, the anti-emetic effects were achieved (presumably via the area postrema) and in the second, positive neurological benefit was derived in the absence of adverse psychological effects.

Is it possible that a differential CB1 receptor distribution appears during development, or that differential maturation of brain pathways is responsible for the clinical success? Clearly, further animal experiments and clinical investigations of cannabinoid treatment in the developing organism are warranted but *Cannabis* exposure prenatally or during adolescence appears to not have a significant effect on development.

**Emergency Room Admissions**

Data on both drug treatment and emergency room admissions also distinguish the abuse potential of marijuana from that of other drugs, and establishes its relative abuse potential as lower than Schedule I drugs such as heroin and Schedule II drugs such as cocaine[462,501,502].

According to the Treatment Episodes Data Set, nearly 54% of all marijuana treatment admissions are referred to by the criminal justice system, compared to much smaller percentages for heroin and cocaine. The abuse potential of the more dangerous drugs is so severe that addicts seek treatment on their own or through persuasion from the people they have contact with. Furthermore, marijuana treatment admissions are much more likely to receive ambulatory drug treatment such as outpatient care than opiate or cocaine admissions, another indication that marijuana has a lower potential for abuse.

The relative abuse potential of drugs can also be evaluated by comparing the likelihood of the respective user populations to be admitted to emergency rooms as a result of their drug use. According to the 1998 National Household Survey, there were 18.7 million annual marijuana users, 3.8 million annual cocaine users, and 253,000 annual heroin users. According to 1998 data from the Drug Abuse Warning Network (DAWN), based on reports from participating hospital emergency rooms, there were 76,870 emergency room mentions for marijuana, 172,014 mentions of cocaine, and 77,645 mentions of heroin/morphine. Incorporating both sets of data indicates that rates of emergency room mentions per 100,000 users is 411 for marijuana, 4,514 for cocaine, and 30,690 for heroin. The table demonstrates that users of marijuana in the U.S. are much less likely to be admitted to emergency rooms than those of cocaine and heroin.

Thus, national survey data provide additional evidence that marijuana does not have a high potential for abuse relative to other controlled substances.
Cannabis Drug Testing and Impairment in Driving and at the Workplace

Access programs for medical and adult use of Cannabis raises questions around the issue of workplace safety and driving. Evidence from traffic and fatality databases suggests that cases of DUI related traffic fatalities and drug overdoses are either not significantly increasing or significantly decreasing in States with Cannabis access program[322,503]. This trend is occurring at a time when toxicology testing for the presence of any Cannabis metabolite is becoming more routine[322,504].

There are concerns regarding the possibly of impaired workers on any medicine or legal drug, presents a dilemma for employers. While drug testing can determine if a worker has consumed Cannabis or any drug, there is no way to determine from drug testing the date & time when the worker took the drug and there is a very poor correlation between impairment and plasma levels of drugs. Plasma, blood, or urine levels of benzodiazepine, cocaine, opiates, anti-depressants and almost every other drug have a very poor correlation with intoxication or impairment[505-512]. Meaning that sobriety testing by a drug test (at work or the roadside) has little meaning in terms of public safety. In fact, using the data on DUI’s in the U.S. in a meaningful way is problematic, in terms of predicting public health harms because DUI’s for a drug are issued for the presence of the drug in a blood or similar test indicating past use within no specific time frame (i.e., sometime during the last month); these DUI’s related to drug testing are not issued based on traffic violations, traffic faults, or any required evidence of actual impairment or intoxication. For example, some U.S. states have a zero tolerance policy, meaning the drug does not have to be quantified or within a limit of quantification, to bureaucratically qualify as intoxication.

Furthermore, toxicology tests like those conducted after a fatal roadside accident typically do not report the levels the drugs, toxicology reports from traffic fatalities do no list the concentration or amount of drugs that were detected in a tissue or fluid, thus the reports are not useful for determining impairment or intoxication[513].

The metabolites of Cannabis products can remain in the body for up to three or even four weeks or months depending on the type of test (hair, urine, blood, etc.), a worker who is not impaired and can safely handle job responsibilities may be at risk of losing his job due to laws not based on any scientific or clinical evidence.

Drug testing, whether based on blood or urine sampling, can detect cannabinoid metabolites for up to 3-4 weeks following consumption. New or occasional users may show impairment at lower concentrations quicker than chronic users, but the minimum amount of time before the drug is no longer detectable in urine or bloodstream is generally at least 3-4 days after use. This indicates workers who fail a drug test for Cannabis metabolites may have no impairment unless they consumed Cannabis shortly before or during work. Both the National Highway Traffic Safety Administration and the National Institute on Drug Abuse have stated that marijuana impairment testing via blood sampling is unreliable[514-517]. Drug tests generally produce false-positive results in 5%-10% of cases and false negatives in 10-15% of cases[518].

The solution to this common challenge of drug testing according to the National Workrights Institute is to implement impairment testing, which has been shown to be more reliable than using a blood, urine, or hair test for an unscientifically determined, detectable amount of a drug[519].
Institute has stated that “the available information indicates that impairment testing is not just a better answer on paper, but in practice as well. Employers who have used impairment testing consistently found that it reduced accidents and was accepted by employees. Moreover, these employers consistently found that it was superior to urine testing in achieving both of these objectives.[520,521].”

There are advantages for impairment testing over blood & urine testing for both employers and employees[522-524]. Impairment testing addresses employer concerns about human safety and protection of property. When employers promote these goals among all employees, it has the potential to reduce unreported accidents. Employees who use medical marijuana will be able to reveal it. In addition, focusing on impairment fulfills the goals of disability discrimination statutes: to protect applicants and employees with a disability who can perform successfully with reasonable accommodations by the employer. According to studies completed by the Workrights Institute: 100% of employers who used impairment testing considered their experience successful. And 82% of employers found that impairment testing improved safety[521].

**FACTOR 7: ITS PSYCHIC OR PHYSIOLOGICAL DEPENDENCE LIABILITY**

**Dependence Liability**

**Basic research on rewarding, tolerance, and withdrawal.**

In recent years, scientists were able to show that animals do self-administer THC under certain conditions. Basic animal research also shows that *Cannabis* produces tolerance and withdrawal. This research helps explain abuse of *Cannabis* and dependency in humans. However, basic research cannot predict how pronounced these effects will be in humans and whether they are stronger or less strong compared to other drugs such as caffeine, nicotine and heroin.

Tanda et al. (2000) demonstrated for the first time that animals self-administer THC. They write in their abstract:

"Many attempts to obtain reliable self-administration behavior by laboratory animals with delta-9-tetrahydrocannabinol (THC), the psychoactive ingredient in marijuana, have been unsuccessful. Because self-administration behavior has been demonstrated in laboratory animals for almost all other psychoactive drugs abused by humans, as well as for nicotine, the psychoactive ingredient in tobacco, these studies would seem to indicate that marijuana has less potential for abuse. Here we show persistent intravenous self-administration
behavior by monkeys for doses of THC lower than doses used in previous studies, but comparable to doses in marijuana smoke inhaled by humans[525]."

In this study Tanda and colleagues used a low but clinically relevant dose of THC administered intravenously in a clear solution. This solution rapidly distributed THC to the brain. Previous attempts to show self-administration, using much higher doses of THC held in a suspension, failed. One reason for this may be that, although higher doses were used, the suspension resulted in less brain penetration. In this study, the monkeys had previously been trained to self-administer cocaine by pressing a lever 10 times. When saline was substituted for cocaine, self-administration stopped. When THC replaced the saline, the monkeys quickly started to press the lever again. The monkeys gave themselves about 30 injections during an hour-long session, which equates roughly with the dose received by a person smoking a marijuana joint.

The team went on to confirm that giving the monkeys a second drug that directly blocks cannabinoid receptors in the brain could prevent self-administration. Dr. Goldberg's team concludes from its observations that THC "has as much potential for abuse as other drugs of abuse, such as cocaine and heroin."

However, Martin Jarvis, professor of health psychology at University College London (UK) said in an interview to the British Medical Journal this would probably overstate the case. He said that misuse is "a judgment best made by looking at patterns of actual human use." He continued: "We shouldn't assume that unreasonable behavior in society follows from the observation of brain reward behavior in animals alone[526]."

Ian Stolerman, professor of behavioral pharmacology at the Institute of Psychiatry in London, agreed with Jarvis and states during the interview: "This is an important study because for the first time it provides a method for studying directly the intake of THC by a laboratory animal and thus models a key behavioral feature of addictive states generally. It will lead to studies of how and where THC works in the brain to generate drug abuse. It does show that THC shares properties with other drugs of abuse, but whether it is really as potentially abusive as cocaine and heroin is not so clear[526]."

Several studies in recent years have demonstrated that there is an interaction between the endogenous cannabinoid system and several other transmitter and modulator systems in the brain, among them the opioid system.

Lichtmann et al. (2001) have shown that there seems to be a reciprocal relationship between the cannabinoid and opioid system relative to dependency[527]. THC was able to block some of the withdrawal symptoms in morphine dependent mice, and morphine was able to reduce some of the withdrawal symptoms in THC dependent mice. The mu-opioid receptor seems to be involved in THC dependence. These findings are consistent with the results of a study by Yamaguchi et al. (2001)[528]. Their study in mice suggests that in morphine dependence, upregulation of cannabinoid CB1 receptors occurs. Thus, CB1 receptor agonists may have potential as therapeutic drugs for opiate withdrawal symptoms. Successful treatment of opiate withdrawal symptoms has been described by physicians of the 19th century and in contemporary case reports.
Valverde et al. (2001) support the concept of an interaction between the cannabinoid and the opiate systems. They found several effects of THC on the opiate system in mice including facilitation of the antinociceptive and antidepressant-like responses elicited by the endogenous enkephalins and increased release of Met-enkephalin-like material in the nucleus accumbens. However, there was no modification of the rewarding responses produced by morphine from the acute or chronic administration of THC.

"Recent studies have suggested that cannabinoids might initiate the consumption of other highly addictive substances, such as opiates. In this work, we show that acute administration of Delta9-tetrahydrocannabinol in mice facilitates the antinociceptive and antidepressant-like responses elicited by the endogenous enkephalins protected from their degradation by RB 101, a complete inhibitor of enkephalin catabolism. This emphasizes the existence of a physiological interaction between endogenous opioid and cannabinoid systems. Accordingly, Delta9-tetrahydrocannabinol increased the release of Met-enkephalin-like material in the nucleus accumbens of awake and freely moving rats measured by microdialysis. In addition, this cannabinoid agonist displaced the in vivo [3H] diprenorphine binding to opioid receptors in total mouse brain. The repetitive pretreatment during 3 weeks of Delta9-tetrahydrocannabinol in mice treated chronically with morphine significantly reduces the naloxone-induced withdrawal syndrome.

However, this repetitive administration of Delta9-tetrahydrocannabinol did not modify or even decrease the rewarding responses produced by morphine in the place preference paradigm. Taken together, these behavioral and biochemical results demonstrate the existence of a direct link between endogenous opioid and cannabinoid systems. However, chronic use of high doses of cannabinoids does not seem to potentiate the psychic dependence to opioids[529]."

The neurotransmitter dopamine seems to play a major role in rewarding by drugs and physical activities, such as sex and sports. It has been suggested that the use of Cannabis, like that of caffeine, tobacco and other drugs, is associated with increased mesolimbic dopamine activity[530]."However, evidence for such an effect is inconsistent[531]." Stanley-Cary et al. (2002) investigated whether or not the cannabinoid agonist CP 55,940, which binds to the CB1 receptor, mimicked the effects of amphetamine, a drug which increases dopamine release, on prepulse inhibition (PPI) of the acoustic startle reflex[531]. They write:

"The first experiment measured the PPI of 16 male Wistar rats injected (i.p.) with different doses of CP 55,940 in a Latin-square design. A second experiment replicated the effects of the first experiment in a between-subjects design, and also examined the effects of using a 5% alcohol solution as a solvent for cannabinoid agonists, in comparison to the more inert detergent, Tween 80. In both experiments, CP 55,940 in Tween 80 significantly reduced basal activity, increased startle onset latencies and increased PPI, effects opposite to those of amphetamine. These results suggest that the net behavioral effects of cannabinoids are opposite to those of amphetamine. In addition, it was found that 1 ml/kg of a 5% alcohol solution has significant behavioral effects on its own, and reverses the effects of CP 55,940 on PPI[531]."
Effects of Cannabis use on dopamine may be complex and are not fully understood today. Studies showed that activation of dopamine receptors with a dopamine (D2-like receptor) ligand in the striatum (a region that controls planning and execution of motor behaviors) led to a strong stimulation of anandamide (an endocannabinoid) outflow[532]. The researchers concluded that the physiological role of anandamide may be "...to counter dopamine stimulation of motor activity. (...) Thus, our findings may have implications for neuropsychiatric disorders such as schizophrenia, Tourette’s syndrome and Parkinson’s disease and may point to novel therapeutic approaches for these conditions[532]."

In another study of this group, elevated endocannabinoid levels were found in the cerebrospinal fluid of people with schizophrenia. One explanation for the higher levels in schizophrenics is that the brain is attempting to compensate for a hyperactive dopamine system[533]. The author suggests that this could be the brain’s response to try and bring this dopamine activity down but in some situations, the brain cannot keep the amount of anandamide high enough to lower dopamine levels[533].

In summary, animal studies show that THC and other ligands to the CB1 receptor are rewarding, that they are self-administered by animals under certain conditions, and that CB1 receptor ligands exert complex interactions with the opiate and the dopamine system. However, determining the relevance and implications of these findings to humans requires clinical studies.

Dependency Compared to other Drugs

Compared to other widely used drugs (alcohol, tobacco, opiates) a smaller percentage of Cannabis users become dependent. Dependency is also less severe compared to many other legal and illegal drugs. The relatively low dependence liability of Cannabis is widely recognized.

Withdrawal from THC has been described in animal research and humans. For example, people who smoke marijuana daily become more aggressive when they quit. Dr. Elena Kouri and colleagues at Harvard University write in the Journal of Psychopharmacology that they had shown objectively that when people stop smoking marijuana, there is a clear withdrawal syndrome[534].

The withdrawal symptoms are relatively mild. In a review of the published literature regarding Cannabis withdrawal symptoms in humans, Smith (2002) stated:

"It is suggested that the studies conducted to date do not provide a strong evidence base for the drawing of any conclusions as to the existence of a cannabis withdrawal syndrome in human users, or as to the cause of symptoms reported by those abstaining from the drug. On the basis of current research, cannabis cannot be said to provide as clear a withdrawal pattern as other drugs of abuse, such as opiates. However, cannabis also highlights the need for a further defining of withdrawal, in particular the position that rebound effects occupy in this phenomenon. It is concluded that more controlled research might uncover a diagnosable withdrawal syndrome in human users and that there may be a precedent for the introduction of a cannabis withdrawal syndrome before the exact root of it is known[535]."
Tolerance and rebound phenomena in humans have been described for Cannabis. These are other indications of dependency caused by Cannabis:

"Tolerance develops to the receptor-mediated effects of THC with continued usage. However, there are distinctions in their degree with different effects. Discontinuation of chronic THC use may cause rebound phenomena (transient increase in intraocular pressure, loss of appetite, etc.). Some chronic users report withdrawal symptoms after abrupt cessation. This withdrawal syndrome is characterized by irritability, agitation, sleep disorder, hyperhidrosis and loss of appetite. It is generally mild. Cannabis dependency is less determined by physical than by psychological factors. Dependency and abuse potential of therapeutically employed ∆9-THC is low."

Dependency rates are reported to be lower than with many other drugs. In a German study of 1,458 current or previous Cannabis users, ordered by the German Federal Health Ministry, 2-10% of those using exclusively Cannabis were classified as substance dependent. If those who also used other illegal drugs were included, 8% of Cannabis users were regarded as dependent, including 1% of the "occasional users," 7% of the "individual users," 10% of the "recreational users," and 28% of the "permanent users." Duration of consumption had no influence on the likelihood of the subject to quit use, an indication that the risk of dependency was independent of duration of use, and that users generally had no problems quitting.

Similar percentages were reported by Hall et al. (1999):

"A variety of estimates have been derived from U.S. studies in the late 1970s and early 1980s, which defined cannabis use and dependence in a variety of ways. These studies suggested that between 10 and 20 per cent of those who have ever used cannabis, and between 33 and 50 per cent of those who have had a history of daily cannabis use, showed symptoms of cannabis dependence (see Hall, Solowij & Lemon, 1994). A more recent and better estimate of the risk of meeting DSM-III criteria for cannabis dependence was obtained from data collected in the National Comorbidity Study (Anthony, Warner & Kessler, 1994). This indicated that 9 per cent of lifetime cannabis users met DSM-R-III criteria for dependence at some time in their life, compared to 32 per cent of tobacco users, 23 per cent of opiate users and 15 per cent of alcohol users."

In the recent past, several studies have attempted to compare the health risks of the most common legal and illegal drugs. Two studies received special attention: a report by order of the French Health Ministry, the so-called "Roques-Report", and a study prepared for the World Health Organization. Major attention was paid to concerns over dependency/addiction potentially having a causative role associated with these drugs.

Both reports concluded that heavy Cannabis consumption causes less harm than heavy use of the most common other legal and illegal drugs. Special attention was paid to the question of dependency and abuse. Hall et al. (1999) concluded that all drugs under investigation can cause dependency.
main health risks to exclusive users of Cannabis would be limited to daily users who consume the drug over a period of several years. These risks included the risk of a dependency syndrome, development of a chronic bronchitis, and involvement in motor vehicle accidents if the user drives under acute influence of the drug. The latter could also affect occasional users. With regard to dependency Hall et al. (1999) conclude (as quoted above):

"A variety of estimates have been derived from U.S. studies in the late 1970s and early 1980s, which defined cannabis use and dependence in a variety of ways. These studies suggested that between 10 and 20 per cent of those who have ever used cannabis, and between 33 and 50 per cent of those who have had a history of daily cannabis use, showed symptoms of cannabis dependence (see Hall, Solowij & Lemon, 1994). A more recent and better estimate of the risk of meeting DSM- R.III criteria for cannabis dependence was obtained from data collected in the National Comorbidity Study (Anthony, Warner & Kessler, 1994). This indicated that 9 per cent of lifetime cannabis users met DSM-R-III criteria for dependence at some time in their life, compared to 32 per cent of tobacco users, 23 per cent of opiate users and 15 per cent of alcohol users[537]."

Eminent addictions specialist Jack Henningfeld was asked to rate the addictive qualities of popular drugs and produced the following ratings according to five general indicators of abuse potential:

- **Tolerance:** How much of the substance is needed to satisfy increasing cravings for it, and the level of stable need that is eventually reached.
- **Dependence:** How difficult it is for the user to quit, the relapse rate, the percentage of people who eventually become dependent, the rating users give their own need for the substance and the degree to which the substance will be used in the face of evidence that it causes harm.
- **Intoxication:** Though not usually counted as a measure of addiction in itself, the level of intoxication is associated with addiction and increases the personal and social damage a substance may do[539].

This assessment agrees with those cited above in that marijuana ranks low on all indicators of additive potential compared to other commonly used drugs. Adolescents are more susceptible to marijuana dependence and to problems related to Cannabis abuse than adults.

"Adolescents are dependent at a lower frequency and quantity of use than adults: the differences diverge as level of use increases. Twice as many adolescents as adults who used marijuana near-daily or daily within the last year were identified as being dependent (35% versus 18%). Frequency and quantity of use each retained a unique effect on dependence, but frequency appeared to be more important than quantity in predicting last year dependence[540].” However, recent evidence has not produced supporting evidence long-term effects related to this finding in other, larger populations[11].

This higher dependence liability of adolescents is sometimes used as an argument against the medical use of Cannabis. However, this argument is not used with other medicines, such as the opiates. The IOM report states that permitting the medical use of Cannabis would not increase non-medical uses. The
report also addresses the suggestion by opponents of medical use that approving marijuana as a medicine "sends the wrong message." The authors say there is "no convincing data to support this concern," and they note that "this question is beyond the issues normally considered for medical uses of drugs[171]."

Kandel et al. (1997) analyzed dependency rates in a sample of about 88,000 individuals[541]. They found that nicotine was the most addictive drug. Analyses were based on three aggregated waves (1991, 1992 and 1993) of the nationally representative samples of the general population, at or above 12 years of age, interviewed in the National Household Surveys on Drug Abuse (n = 87915).

"The five major findings are that: (1) nicotine is the most addictive of the four drugs we examined; (2) among female last year users of alcohol and marijuana, adolescents are significantly more at risk for dependence than any other age group of women; (3) conditional prevalences of last year dependence on alcohol, marijuana and cocaine are higher among adolescent females than adolescent males but significantly different only for cocaine; (4) among adults, the rates of dependence are higher among males than among females for alcohol and marijuana, but lower for nicotine; and (5) among last year users, whites are more likely than any other ethnic group to be dependent on nicotine and blacks to be dependent on cocaine[541]."

If selected samples of individuals are investigated, it is necessary to avoid any generalization of the results. Crowley et al. (1998) investigated a sample of young Cannabis users (age: 13- 19 years) with serious Cannabis-use disorders and problems and noted[542]:

"The prevalence of cannabis use is rising among adolescents, many of whom perceive little risk from cannabis. However, clinicians who treat adolescent substance users hear frequent reports of serious cannabis-use disorders and problems. (...) The data indicate that for adolescents with conduct problems cannabis use is not benign, and that the drug potently reinforces cannabis-taking, producing both dependence and withdrawal. However, findings from this severely affected clinical population should not be generalized broadly to all other adolescents[542]."

In conclusion, Cannabis can cause dependency but withdrawal is milder than withdrawal from several other legal and illegal drugs, and dependency is less frequent than with most other common legal and illegal drugs.

**FACTOR 8: WHETHER THE SUBSTANCE IS AN IMMEDIATE PRECURSOR OF A SUBSTANCE ALREADY CONTROLLED**

While Cannabis is not an immediate pre-cursor to a scheduled drug, purified-CBD can be converted into THC.
IV. FINDINGS AND RECOMMENDATIONS

We support the removal of Cannabis from Schedule I and the placement into a category, which recognizes its inherent safety and medical utility.

To reside in Schedules II-IV and be approved for diagnosing, mitigating, treating, or curing a specific medical condition, a substance or botanical must proceed through a rigorous FDA process proving safety and efficacy. Different forms of Cannabis have been through rigorous clinical testing including whole plant Cannabis, hash oil extracts dissolved in ethanol, and purified extracts.

To be approved a medicine the FDA requires the following five criteria to be addressed; Based on the information from this eight factor analysis, below are the five criteria the FDA requires to be satisfied to demonstrate that Marijuana or Cannabis is medicine:

(1) THE DRUG’S CHEMISTRY IS KNOWN AND REPRODUCIBLE.

The chemistry of Cannabis is known and reproducible. Cannabis monographs have been published by the AHP setting guidance for standards of identity, analysis, quality control, administration, and dosing. The AHP monographs are based on FDA and USP guidelines for botanical medicines. Additionally, standardized Cannabis products are available from the NIDA-funded University of Mississippi marijuana farm for the FDA’s IND program, a program that has provided standardized Cannabis cigarettes to the same participants, every month for decades. Furthermore, the Research Triangle Institute (A NIDA funded, DEA compliant organization) has also released a quality control manual for Cannabis, entitled The Analytical Chemistry of Cannabis – Quality Assessment, Assurance, and Regulation of Medicinal Marijuana and Cannabinoid Preparations.

Internationally, private companies have completed clinical studies and successfully marketed standardized Cannabis products (Cannabis flowers, extracts, and nabiximols) in 27 countries. In the last decade, the U.S. has approved over 550 studies of marijuana or Cannabis, 144 with dronabinol or tetrahydrocannabinol (THC), and 96 with pure CBD or a CBD-rich Cannabis extract according to clinicaltrials.gov.

Cannabis is dispensed in pharmacies throughout Europe and at dispensaries in the U.S., which conforms to standards that would qualify the Cannabis products as botanical medicines based on existing safety guidelines from the FDA, AHP, and the U.S. Department of Agriculture (USDA). The quality and safety of medical Cannabis and its derivatives are adequately addressed by existing national and local standards. The standards also address best practices for Cannabis operations, such as manufacturers, cultivation sites, laboratories, and dispensaries. Botanical medicines and herbal products are regulated; many of these botanical safety standards are directly applied to medical Cannabis. Several countries have made significant regulatory efforts to enact the existing national and local level standards for Cannabis production and distribution[57,214,543].
Some countries have published monographs (i.e., Czech Republic, Holland, U.S., and Canada) to specifically address the quality control of Cannabis, including methodology. Trade associations have published best practices for cultivation, dispensing, manufacturing and laboratory practices[544]. Furthermore, an abundance of national and international guidance documents provide quality control standards that address nearly every aspect of quality control and product safety for botanical substances, such as Cannabis and its derivatives.

One hurdle to quality control of medical Cannabis products is the present control status of Cannabis in countries such as the U.S. and also the controls under the conventions. National and international controls prevent adequate product testing in U.S. Cannabis programs and may inadvertently jeopardize public health. There has only been a single study, which examined the labeling accuracy (i.e., potency) of the Cannabis products' accessed through three state programs in the U.S. The study demonstrated that medical Cannabis product labels in the U.S. can be inaccurate [545]. However, the study also demonstrated that the current national controls for Cannabis impair the ability to address Cannabis product public health concerns.

The DEA controls the release of analytical-quality standards for calibrating scientific instruments, which can only be purchased in necessary amounts if the operation has received a Schedule I license from the DEA. The DEA will not grant a Schedule I license to a state sponsored medical Cannabis laboratory, because the laboratory would receive medical Cannabis samples for analysis from non-DEA licensed sources (such as State licensed manufacturers, distribution centers, cultivation sites, patients, or doctors that recommend Cannabis to patients). Therefore, the Schedule I status of Cannabis blocks most laboratories from determining the precise potency of the product. It is difficult to address public health issues regarding medical Cannabis products while it remains in Schedule I status. However, testing for clinically relevant contaminants – such as heavy metals, bacteria, and fungus – can proceed without requiring DEA licensing but this product safety testing is also vulnerable to DEA or federal interference due to the scheduling status.

A normalizing factor for a medicine like Cannabis in the U.S. could be for the USP to create a Cannabis monograph; these standards would be adopted to regulate Cannabis as a medicinal product nationally[546]. However, this action would grant pharmacists in the U.S. the ability to work with Cannabis, which is forbidden by the DEA. Hence, the USP cannot create a Cannabis monograph and still maintain compliance with the DEA.

Presently, the USP defers to the AHP monograph as the current standard for Cannabis products in the U.S.[7]. A recent meeting of the USP suggests drafting of the document will not begin until Cannabis is rescheduled to a status that recognizes its medicinal use and outstanding safety profile. The standards issued by the AHP monograph and American Herbal Products Association (AHPA) have been adopted by 16 U.S. states to regulate product safety for their medical Cannabis programs. Furthermore, AHPA, the trade association for the herbal products industry, has issued its medical marijuana manufacturing guidelines, completing its series of recommendations for state regulators in the areas of manufacturing, packaging and labeling, cultivation, dispensary operations, and laboratory practices.

Another example of production with good quality assurance/quality control is the Dutch program for
medicinal Cannabis. This is produced under responsibility of the Ministry of Health and meets a number of quality requirements: consistent strength on THC and composition of secondary cannabinoids, absence of microbiological contamination, pesticides and heavy metals, and humidity. Where there is a norm provided in the European Pharmacopoeia, this norm is followed[547].

The next sections briefly discuss published resources and guidance documents being used by governments to provide quality control and product safety around the world for agricultural products and botanical medicines, including Cannabis.

**Good Agricultural and Collection Practices**

The quality of raw material for botanical medicine can be safeguarded by using Good Agricultural and Collection Practices (GACP aka GAP) to the extent possible in all aspect of growing, harvesting, and storage[548]. Specific guidelines for regulators regarding Cannabis cultivation practices in the U.S. have been published by AHPA. These standards include requirements for standard operating procedure documentation, employee safety training, security, and batch tracking[544]. The American Herbal Pharmacopoeia has also released standards of quality control for Cannabis cultivation.

In The Netherlands, Czech Republic, and Italy, Cannabis to be used by patients, must be produced under GMP-like conditions. All products have to be fully tested (by an independent laboratory) per batch on cannabinoid content, absence of heavy metals, aflatoxins, pesticides (residue), and microbes to a level of <10 cfu. Standardization of Cannabis and Cannabis derivatives according to the monograph of herbal medicines of the European Medicine Agency (EMA) is mandatory and has to be proven for each batch.

In Austria (AGES) and the UK (GW Pharmaceuticals Ltd), Cannabis has to be produced under GAP; however, the derivatives from this Cannabis must be produced under GMP. Finished products need to be standardized according to regular [pharmaceutical] products.

**Good Manufacturing Practice for Cannabis**

Many guidance documents are available for reference and use in the manufacturing of plant medicines and products, any facility manufacturing products for human consumption should follow GMP. WHO has published guidelines on manufacturing botanical and herbal medicines, and the U.S. FDA has published guidance documents as well[549-552]. The AHPA manufacturing guidelines have a specific procedure for the recall of medical Cannabis products that do not meet “appropriate standards of identity, purity, strength, and composition and their freedom from contamination or adulteration.” The AHP Cannabis monograph also sets limits for residues such as solvents and pesticides, heavy metals, bacteria, and fungi[214].

**Good Laboratory Practices**

Methods used to determine potency should be scientifically validated by laboratories for several criteria including but not limited to specificity, linearity, accuracy, precision, and ruggedness. The FDA and other organizations (i.e., AHPA, USP, and AHP) have provided guidance documents that represent the current thinking on method validation and other aspects of good laboratory practices. There are also...
international standards for analyzing medical *Cannabis* products, which have been issued, for example, by the UN’s Office of Drugs and Crime in their document entitled “Recommended Methods for the Identification and Analysis of *Cannabis* and *Cannabis* products”[553].

Below are a few examples of applicable guidance from a regulatory perspective, for analytical method validation for new methods, or methods not outlined in existing international and national regulatory documents:

- **USP–NF, Validation of Compendial Methods; USP pharmacopeia 35, United States Pharmacopeia Convention, Inc., Rockville, MD. May 1, 2012 – December 1, 2012.**
- **U.S. FDA, Center for Drug Evaluation and Research (CDER), Reviewer Guidance on Validation of Chromatographic Methods, November 1994.**
- **American Herbal Pharmacopoeia *Cannabis Inflorescence*. Standards of Identity, Analysis, and Quality Control (2013).**

Quality control and quality standards for medicinal *Cannabis* have been developed and adopted by over 16 U.S. states, and many countries such as Canada, Israel, the Netherlands, and the Czech Republic to name a few. The current standards are presently being appropriately applied or implemented through third party licensed certification bodies, for regulating *Cannabis* and *Cannabis*-related products for human consumption.

The adopted product safety standards require *Cannabis* operations to implement quality control/quality assurance programs, batch tracking, adverse event tracking, employee safety training, and documentation of all relevant operational procedures, among several other criteria. The AHP and AHPA documents point to Patient Focused Certification (PFC) for implementation of these standards. PFC has offices in Washington, DC and the Czech Republic. PFC is the only international program that can verify that a country, region or state’s *Cannabis* standards are being followed ([www.patientfocusedcertification.com](http://www.patientfocusedcertification.com)). PFC conducts a physical (site or facility) and documentation audit of the operation to generate an audit report that is submitted to a review board. PFC’s review board features experts that have served in regulatory and scientific roles in U.S. presidential administrations, at the USDA, in quality control laboratories, and related disciplines. PFC audited its first *Cannabis* operations in the U.S. in 2013 and in Europe in 2015, and is now an option for regulators in every country, state, or region with medical *Cannabis* access programs.

A successful public health outcome of product safety regulations has been demonstrated through successful product recalls in Canada and the U.S. This required the cooperation of government, manufacturers, and 3rd party certifying bodies that resulted in consumer protection[554-560].

To address public health concerns regarding the increasing availability of medical *Cannabis* products, the scheduling status of *Cannabis* needs to be thoughtfully and deliberately rescheduled, in order for producers, cultivators, manufacturers, laboratories, clinicians, researchers, and regulators to fully implement quality control standards for medical *Cannabis* products. Additionally, the UN Conventions allow for governments to issue multiple licenses to cultivate or produce *Cannabis*. 
(2) THERE ARE ADEQUATE SAFETY STUDIES.

Cannabis products have been on the market for decades and have shown acceptable safety standards for use under medical supervision. Smoked, vaporized, or ingested marijuana can deliver consistent amounts of active chemicals and a toxic lethal overdose of Cannabis is not achievable.

Sixteen states have adopted the national standards and guidance provided by the AHPA Cannabis Best Practices documents and the American Herbal Pharmacopoeia Cannabis Inflorescence Standards of Identity, Analysis, and Quality Control monograph. Federal standards are not available for Cannabis and will not be produced by the USP while the plant is Schedule I because the USP would fall out of compliance with Drug Enforcement Administration (DEA) standards. The FDA has approved several Cannabis studies and a new IND program with a Cannabis extract (marketed as Epidiolex) that is currently being administered to children in hospitals across the U.S.

While street marijuana has a high potential for abuse, standardized Cannabis products do not have a high potential of abuse, have been on the market for decades in the U.S. (Marinol and Nabilone), and whole-plant Cannabis medicines are available in 27 other countries (Bedrocan and Nabiximols) [60]. Commonsense dictates that self-administration with unstandardized street drugs has a high potential for abuse but the data addressing Cannabis does not report or document nor support the notion of significant abuse or divergence with standardized Cannabis products. Cannabis should be rescheduled because standardized preparations have a well-documented low potential for abuse and a low street value or resale value.

Summaries on the toxicology of Cannabis are listed below. For references on human toxicology research and Cannabis please visit [http://american-safe-access.s3.amazonaws.com/criticalreviewFINAL.pdf]:

- Based on current understanding of basic toxicity research – sedation, cytotoxicity, genotoxicity, etc. – Cannabis and its components seem to have a uniquely wide safety margin [36–39]. To date, there has never been a single well-documented case of human fatality attributable to an overdose of Cannabis or its components, and no experimental or non-extrapolated LD_{50} can be attributed to a toxic or lethal overdose of Cannabis or a preparation thereof.

- No scientifically significant negative neuropsychological sequelae have yet been attributable to Cannabis usage. Arguably, some of these studies remain limited by a number of factors that need to be controlled in future investigations. Primarily, Cannabis use and dosing needs to be confirmed in users with biological and chemical tests, as issues of dosing and patterns of use are confounding factors when not adjusted for. The meta-analytical study of long-term Cannabis use on neurocognitive functioning, results failed to find any substantial, systematic effect on users who were not concurrently intoxicated.

- Claims of brain damage and cerebral atrophy are not supported by current evidence. When controlling for pertinent variables such as age, gender, and history of alcohol use, research has not
been able to show any association between the use of Cannabis and changes in brain structures[59].

- Short-term use of existing standardized medical Cannabis and Cannabis products appear to increase the risk of non-serious adverse events. Risks associated with long-term Cannabis use are poorly characterized in published clinical trials and observational studies; however, the cognitive effects observed in long-term users do not appear to be permanent in nature[40]. With the exception of very limited studies on synthetic endocannabinoid system modulators, Cannabis medicines do not appear to cause significant serious adverse events.

(3) THERE ARE ADEQUATE AND WELL-CONTROLLED STUDIES PROVING EFFICACY.

To date, more than 30,000 modern peer-reviewed scientific articles on the chemistry and pharmacology of Cannabis and the cannabinoids have been published, and more than 1,500 articles investigating the body's natural endocannabinoids are published every year. In recent years, modern gold-standard placebo-controlled human trials have also been conducted.

At the time of writing this document, according to clinicaltrials.gov, there are hundreds of approved human research studies. These studies are currently either completed, recruiting, approved, or in process. A total of 144 are approved for THC, 96 are approved for CBD, and 559 are approved for marijuana or Cannabis. Due to Schedule I status, medical Cannabis preparations such as nabiximols and CBD-rich extracts are imported and cannot be manufactured in the U.S., even though they are licensed pharmaceutical products.

There is a wealth of clinical information available on the uses of standardized medical Cannabis products. The FDA has approved new drug applications for Cannabis products. For example, a CBD-rich extract (marketed as Epidiolex) is an imported, purified Cannabis extract that has been approved for clinical use in children and is currently in clinical practice across several institutions in the U.S. Additionally, an inhaled Cannabis study has recently been approved for investigating therapeutic effects in PTSD.

Cannabis currently has accepted medical uses in 41 states and the District of Columbia. Cannabis and its products have mandatory testing requirements. A Cannabis nabiximol, a whole-plant ethanolic extract, has generated more than 9,000 patient/years of modern clinical data for the treatment of chronic pain[126].

A 2009 review of clinical studies conducted over a 38-year period found that “nearly all of the 33 published controlled clinical trials conducted in the U.S. have shown significant and measurable benefits in subjects receiving the treatment[148].” The review’s authors made particular effort to note that cannabinoids have the capacity for analgesia through neuromodulation in ascending and descending pain pathways, neuroprotection, and by anti-inflammatory mechanisms – all of which indicate that the cannabinoids found in Cannabis have applications in significantly managing chronic pain, muscle spasticity, cachexia, and other variously debilitating conditions.

Currently, Cannabis is most often recommended as a complementary or adjunctive medicine. However, there exists a substantial consensus amongst experts in the relevant disciplines – including the American
College of Physicians – that Cannabis and cannabinoid-based medicines have undeniable therapeutic properties that could potentially treat a variety of serious and chronic illnesses.

(4) THE DRUG IS ACCEPTED BY QUALIFIED EXPERTS.

In this document, under the section entitled “List of Medical and Scientific Organizations that have Issued Letter of Support for Medical Cannabis” are over 200 medical, scientific, health professionals, religious and community organizations who accept Cannabis as a medicine and have issued letters in support of this medicine (http://www.medicalcannabis.com/about/health-care-professionals/supporting-organizations/)

Medical schools are teaching required coursework which includes the endocannabinoid system and the therapeutic applications of Cannabis. For example, theanswerpage.org, a Harvard University based CME, is educating physicians about the benefits of the medical uses of Cannabis. This has led to the creation of clinical Cannabis certification for physicians; an educational program that is required for physicians to recommended medical cannabis in states such programs (http://cannabiscarecertification.org).

(5) THE SCIENTIFIC EVIDENCE IS WIDELY AVAILABLE.

One of the criteria preventing the rescheduling of Cannabis is the notion that information about this medicine is not widely available. There are tens of thousands of peer reviewed articles available through online portals, journal websites, and other resources for health professionals to access clinical information about Cannabis, including but not limited to: Springer, Wiley, Pubmed, Public Libraries, medical and graduate school libraries, and websites of expert groups such as Americans for Safe Access, theAnswerpage.org, and the International Cannabis and Cannabinoid Institute.

The Internet has also revolutionized research and science by allowing the generation of and access to large amounts of information that would have previously been nearly impossible to obtain. People across the globe can now access hordes (a search for ‘cannabis research’ through web of science yields 120,000 articles) of previously unavailable scientific and clinical information.
